ABSTRACT

In a two-layer model with a rigid surface and a flat bottom on an f -plane, an internal Kelvin wave is forced by quasi-geostrophic, mesoscale meanders of a coastal current. These meanders are assumed to be quasi-periodic along the coast, forming a cluster with an alongshore length $1/Ro$ times as long as the meander scale, where Ro is a small Rossby number ($Ro \ll 1$).

The Kelvin wave solution has a form in which the pressure on the coast has a small ($\sim Ro$) alongshore gradient with an ~ 1 amplitude variation over many meander length scales. It is suggested that the boundary condition for a coastal current should satisfy the balance between the (ageostrophic) pressure gradient and the acceleration.
