Five period measures of longevity

John Bongaarts¹

Abstract

This study provides a summary of recently proposed alternatives period measures of "longevity" and assesses whether empirical differences between these measures are consistent with predictions from analytic studies. Particular attention is given to the tempo effect. Three of the five period measures are virtually equal to one another in a simulated population in which mortality follows a Gompertz model with a constant rate of improvement. Similar results are observed among females in Denmark, England and Wales and Sweden in the last quarter century. However, these three measures differ substantially from the conventional period life expectancy when mortality changes over time. These findings are consistent with theoretical analysis by Bongaarts and Feeney (2002, 2003, 2005) which demonstrated that this deviation is caused by a tempo effect whose size varies with the rate of change in mortality.

¹ Population Council, E-mail: jbongaarts@popcouncil.org

1. Introduction

The most widely used measure of period mortality is life expectancy at birth calculated with a conventional life table. Alternative period measures of “longevity” exist, but have found very limited application. The purpose of this note is to provide a brief summary of recently proposed alternatives and to assess whether empirical differences between these measures are consistent with predictions from analytic studies. Particular attention will be given to the tempo effect as a cause of differences between measures. Comparisons rely on simulations in which the force of mortality follows a Gompertz model with a constant rate of improvement over time. Empirical estimates are also provided for three countries with long historical data series. A brief concluding comment summarizes the main reasons why certain measures differ and why others are nearly the same.

2. Definitions of period longevity measures

1) Life expectancy

$$e_0(t) = \int_0^{\infty} \exp\left\{-\int_0^x \mu(a,t) da\right\} dx \quad (1)$$

where $\mu(a,t)$ is the force of mortality at age a and time t . Standard demographic text books (e.g. Preston et al. 2001) discuss the calculation of this conventional measure. Estimates of e_0 are available for most countries of the world (United Nations, 2003)

2) Cross-sectional average length of life (Brouard 1986, Guillot, 2003)

$$CAL(t) = \int_0^{\infty} p_c(a, t-a) da \quad (2)$$

where $p_c(a, t-a)$ equals the proportion of survivors at age a and time t for the cohort born at time $t-a$. $CAL(t)$ sums proportions of cohort survivors at time t and it therefore equals the size of the population at time t in a closed population in which births have occurred at a constant rate of 1 per year in the past.

3) Tempo adjusted life expectancy (Bongaarts and Feeney 2003; Vaupel, 2005)

$$e_0^*(t) = \int_0^{\infty} \exp\left\{-\int_0^x \frac{\mu(a,t)}{1-r(t)} da\right\} dx \quad (3)$$

This is a variant of the conventional period life expectancy, but the tempo effect in the force of mortality is removed by dividing this rate by $1 - r(t)$. The variable $r(t)$, which is assumed to be the same for all ages, denotes the increments to life (or the delay in deaths) due to mortality improvements at time t . Vaupel (2005) refers to $e_0^*(t)$ as the “true life expectancy.” Bongaarts and Feeney (2003) estimate $r(t)$ as

$$r(t) = \frac{dCAL(t)}{dt} \quad (4)$$

This estimate holds in populations in which the function $p_c(a, t - a)$ shifts to higher and lower ages over time while maintaining its shape as longevity rises or falls. Bongaarts and Feeney (2003) examine this so-called “shifting assumption” and demonstrate that it provides a good approximation of observed patterns of adult mortality in recent decades in three high income countries.

4) Lagged cohort life expectancy (Bongaarts and Feeney 2005; Goldstein 2005; Rodriguez 2005)

$$LCLE(t) = e_0^c(c) = e_0^c(t - e_0^c(c)) \quad (5)$$

LCLE at time t is estimated as the life expectancy of the cohort born at time c with the lag between t and c equal to the life expectancy of the cohort: $c = t - e_0^c(c)$. *LCLE* equals the life expectancy of the cohort that reaches its mean age at death at time t .

This measure is similar to one proposed and used by Ryder (1980) to study fertility trends. In Ryder’s analysis of tempo effects in fertility he compared the quantum and tempo observed at time t with the quantum and tempo of the cohort born M years ago where M equals the mean age at birth for the cohort. In the mortality process there are no cohort quantum effects, but period and cohort tempo may be compared with (5).

5) Average weighted cohort life expectancy (Schoen and Canudas-Romo, 2005)

$$ACLE(t) = \int_0^{\infty} w(a,t) e_0^c(t-a) da \quad (6)$$

where $w(a,t)$ are the weights for the life expectancy of cohorts born at time $t - a$. Schoen and Canudas-Romo (2004) estimate these weights as

$$w(a,t) = \frac{p_c(a,t-a)}{CAL(t)} \quad (7)$$

Thus, $ACLE(t)$ equals the weighted average of the life expectancies of the cohorts present at time t , with each cohort weighted by its probability of survival to time t .

The following empirical analysis will be limited to these five measures although others have been proposed (see for example Bongaarts and Feeney 2003) and variants of these five might be constructed (e.g., alternative weights for $ACLE(t)$).

3. Results

To compare these five period indicators simulations are used in which mortality follows a Gompertz model with a constant rate of improvement over time. Following the basic model of Vaupel (1986) as extended by Schoen et al. (2004), the force of mortality at time t and age a is given by

$$\mu(x) = \alpha e^{\beta x} e^{-\rho t} \quad (8)$$

where α and β are the Gompertz level and slope parameters, and ρ equals the rate of mortality improvement. These parameters are held constant throughout a simulation.

Each simulation calculates the five longevity measures for a 50-year period using $\alpha = 0.00001887$ and $\beta = 0.1$. With these parameter values $e_0(t)$ equals 80.0 years at time $t=0$. The trend in $e_0(t)$ during the 50 year simulation depends on the rate of mortality improvement. With $\rho = 0$, $e_0(t)$ remains constant, with $\rho = 0.01$ it rises linearly to 85 years and with $\rho = 0.02$ it rises linearly to 90 years. The simulation results are presented in Table 1. Figure 1 plots values for $\rho = 0.02$.

In the absence of mortality change ($\rho = 0$) all five period measures are constant and equal to one another (first panel of Table 1). With declining mortality ($\rho > 0$)

differences arise, but three of the measures are nearly equal to one another throughout the simulation period:

$$CAL(t) \approx e_0^*(t) \approx LCLE(t) \tag{9}$$

However, $e_0(t)$ is higher than these three measures and $ACLE(t)$ is much higher still.

The simulations in Table 1 were repeated for different values for α, β with similar results. Lower values of α raised all estimates for all measures by the same amount, but kept the difference between them unchanged. Variations in β also made a difference but results will not be presented here because empirical estimates differ little from 0.1. The effect of changes in values of β as well as ρ can be estimated with an equation obtained by Bongaarts and Feeney (2002). They prove that the difference $e_0(t) - e_0^*(t)$ (called the tempo effect) can be estimated as $-\ln(1 - de_0^*(t) / dt) / \beta = -\ln(1 - \rho / \beta) / \beta$ if mortality follows a Gompertz pattern with a constant rate of change in the force of mortality. According to this equation the difference between $e_0(t)$ and $e_0^*(t)$ equals 1.05 years when $\rho = 0.01$ and 2.23 years when $\rho = 0.02$ (assuming $\beta = 0.1$). These analytic estimates agree closely with the simulation results in Table 1.

Table 1: Values of five period longevity measures in Gompertz model with declining mortality

Time, t	$e_0(t)$	$CAL(t)$	$e_0^*(t)$	$LCLE(t)$	$ACLE(t)$
$\rho = 0$					
0	80.00	80.00	80.00	80.00	80.00
25	80.00	80.00	80.00	80.00	80.00
50	80.00	80.00	80.00	80.00	80.00
$\rho = 0.01$					
0	80.00	78.96	78.96	78.97	83.23
25	82.50	81.46	81.45	81.46	85.87
50	85.00	83.95	83.95	83.96	88.50
$\rho = 0.02$					
0	80.00	77.80	77.79	77.84	87.25
25	85.00	82.79	82.78	82.81	92.88
50	89.99	87.78	87.77	87.79	98.50

Figure 1: Trends in five period longevity measures in a Gompertz model with declining mortality ($\alpha=0.000018866$, $\beta=0.1$, $\rho=0.02$)

Figures 2a, b, c plot estimates of four of the five period measures of longevity for females in Denmark, England and Wales, and Sweden from 1925-2000. Each measure is calculated with $\mu(a,t) = 0$ for $a < 30$ to insure that the shifting assumption holds approximately. $ACLE(t)$ is not included because its estimation requires projections of future mortality for more than a century. The results are consistent with the simulations: conventional life expectancy is higher than the other measures and $CAL(t) \approx e_0^*(t) \approx LCLE(t)$ in recent decades.

Figure 2a: Trends in alternative period measures of longevity for females in Denmark, 1925-2000. No mortality under age 30.

Figure 2b: Trends in alternative period measures of longevity for females in England and Wales, 1925-2000. No mortality under age 30.

Figure 2c: Trends in alternative period measures of longevity for females in Sweden, 1925-2000. No mortality under age 30.

4. Discussion

A detailed discussion of the alternative longevity measures and their strength and weaknesses is beyond the scope of this descriptive note, and only brief comments on the most noteworthy findings will be provided.

First, in the simulations, three of the period longevity indicators $CAL(t)$, $e_0^*(t)$ and $LCLE(t)$ are virtually identical to one another. This finding is consistent with the analytic results by Bongaarts and Feeney (2003) who prove that $CAL(t) = e_0^*(t)$ in populations in which the shifting assumption holds. As noted, $p_c(a, t - a)$ is assumed to shift to higher and lower ages over time as longevity rises or falls. In the simulations based on the Gompertz model presented in Table 1, this shifting assumption is very closely approximated except at ages near zero. The error is small because the force of mortality around age zero is very small for a Gompertz with the parameter values used here. The finding that lagged cohort life expectancy $LCLE(t)$ is virtually identical to $CAL(t)$ is expected from Goldstein (2005) and Rodriguez (2005) who prove that $LCLE(t) = CAL(t)$ if the shifting assumption holds and if the shift is linear (i.e. annual

changes in $CAL(t)$ are constant). This result is also consistent with the analysis of cohort and period tempo of fertility by Ryder (1980).

Second, the conventional life expectancy at birth $e_0(t)$ is substantially higher than three other period measures $CAL(t)$, $e_0^*(t)$ and $LCLE(t)$. The difference between $e_0(t)$ and $e_0^*(t)$ is constant throughout the simulation but varies with the rate of improvement in mortality: it equals 2.2 years with $\rho = 0.02$, 1.05 years with $\rho = 0.01$ and 0 when $\rho = 0$. These findings are consistent with the mortality tempo effect described by Bongaarts and Feeney (2002, 2003, 2004).

Third, the weighted average cohort life expectancy $ACLE(t)$ is much higher than the other four indicators. This difference is not surprising since the weights applied to the life expectancies of cohorts alive at time t are highest for the youngest (i.e. most recent) cohorts. As a consequence, this measure is heavily influenced by the mortality that young cohorts will experience in the future. This is confirmed by Schoen and Romo (2004) who conclude that $ACLE$ is roughly the arithmetic mean of the period life expectancy at time t and the cohort life expectancy of the cohort born in year t .

The empirical results for females in Denmark, Sweden, and England in Figure 2 are similar to the simulation findings for recent decades i.e., since approximately the 1970s. However, in earlier decades, differences between $CAL(t)$, $e_0^*(t)$ and $LCLE(t)$, while still small, are no longer negligible. The probable reason for the modest divergence between $CAL(t)$ and $e_0^*(t)$ before ca.1970 is that the shifting assumption is then less accurate. The reason for the appearance of a small but significant divergence between $CAL(t)$ and $LCLE(t)$ in the earlier period is presumably that the assumption of linear change in $CAL(t)$ is more accurate later than earlier in the last century.

5. Conclusion

Three of the five period measures of longevity are virtually equal to one another in a population in which mortality follows a Gompertz model with a constant rate of improvement. Similar results are observed among females in Denmark, England and Wales and Sweden in last quarter century. This equality is as expected from earlier analytic work by Bongaarts and Feeney (2002, 2003, 2005), Goldstein (2005) and Rodriguez (2005). The finding that these three measures differ substantially from the conventional period life expectancy when mortality changes over time is consistent with theoretical analysis by Bongaarts and Feeney (2002, 2003, 2005). They demonstrate that the deviation of $e_0(t)$ from the other period longevity measures is caused by a tempo effect whose size varies with the rate of change in mortality.
