**Abstract.** To achieve secure data communications, two parties should be authenticated by each other and agree on a secret session key by exchanging messages over an insecure channel. In this paper, based on the bilinear pairing, we present a new two-party authenticated key agreement protocol, and use the techniques from provable security to examine the security of our protocol within Bellare-Rogaway model.

## 1 Introduction

In the area of secure communications, key agreement protocol is one of the most important security mechanisms, by which a pair of users that communicate over a public unreliable channel can generate a secure session key to guarantee the later communications' privacy and data integrity. The first pioneering work for two-party key agreement is the Diffie-Hellman protocol given in their seminal paper in 1976 [14]. However, the basic Diffie-Hellman protocol doesn't provide the authentication mechanism, and therefore easily suffers from the "man-in-the-middle" attack and other attacks. To solve this issue, over the past years, a bulk of two-party key agreement protocols with authentication function have been developed [8, 2, 6, 16, 7].

The pairing, which was initially used to reduce the discrete logarithm problem on some elliptic curves (e.g., the super-singular curves) to the discrete logarithm problem on some finite field, had hindered the researchers from building cryptosystems on such these curves until Joux [15] used the pairing to propose the first one round tripartite key agreement protocol in 2000. Since then, due to its *merits*, the pairing has become an important tool for construction of ID-based cryptographic schemes and others. As regards the research of protocol design, many pairing-based two-party authenticated key agreement (AKA) protocols have been proposed [18, 13, 17, 12] in recent years. Smart [18] proposed

an ID-based authenticated key agreement protocol from pairing, but the protocol doesn't provide the perfect full forward secrecy. Chen and Kudla [13] also used the pairing to propose an ID-based authenticate key agreement protocol. Although Chen and Kudla [13] proved that their protocol was secure in the Bellare-Rogaway model [8], yet Cheng et al. [11] pointed out that the proof in [13] is flawed and their protocol was not secure against key revealing attacks. Another ID-based authenticated key agreement protocol from pairing was proposed by McCullagh and Barreto [17], but it can't resist the key revealing attacks pointed out by Choo [10], though it is *proved* to be secure [17] in Bellare-Rogaway model. More recently, Choi et al. [12] have used the pairing to put forth a new ID-based authenticate key agreement protocol for low-power mobile devices. Although the protocol is very efficient, yet it only achieves half forward secrecy in the sense that exposure of client's private key doesn't reveal the previous session keys, while exposure of server's private key does affect the security of the previous session keys.

Motivated by the mentioned above, in this paper, we would like present a new pairing-based two-party authenticated key agreement protocol and use the techniques from provable security to analyze the security of our proposed protocol within Bellare-Rogaway model. Compared with Choi et al. [12] protocol, our protocol provides the full forward secrecy.

The rest of the paper is organized as follows. In section 2, we first recall the security model for two-party authenticated key agreement protocols. Then, we briefly review the bilinear pairing and computational Diffie-Hellman assumption in section 3. We introduce our proposed pairing-based authenticated key agreement protocol in section 4 and give its security analysis in section 5. Finally, we draw our conclusions in section 6.

## 2 Model

In this section, we recall the security model for two-party authenticated key agreement protocols proposed by Bellare and Rogaway [8], modified by Blake-Wilson et al. [2, 6] and others [17, 12]. In the model, the players do not deviate from the protocol and the adversary, whose capabilities are modelled through a pre-defined set of oracle queries, is not a player, but does control all the network communications.

### 2.1 Security Model

**Players.** We assume that two users $A$ and $B$ participate in the key agreement protocol $\mathcal{P}$. Each of them may have several *instances* called oracles involved in distinct executions of $\mathcal{P}$. We denote instance $s$ of $i \in \{A, B\}$ by $\Pi_i^s$ for an integer $s \in \mathbb{N}$. We also use the notation $\Pi_{A,B}^s$ to define the $s$-th instantiation of $A$ executing $\mathcal{P}$ with $B$.

**Adversarial Model.** We allow a probabilistic polynomial time (PPT) adversary $\mathcal{F}$ to access to all message flows in the system. All oracles only communicate with each other via $\mathcal{F}$. $\mathcal{F}$ can replay, modify, delay, interleave or delete messages.

At any time, the adversary $\mathcal{F}$ can make the following queries:

- **Execute**($A$, $B$): This query models passive attacks, where $\mathcal{F}$ gets access to an honest execution of $\mathcal{P}$ between $A$ and $B$ by eavesdropping.
- **Send**($\Pi_i^s, m$): This query models $\mathcal{F}$ sending a message $m$ to instance $\Pi_i^s$. The adversary $\mathcal{F}$ will get back the response of $\Pi_i^s$, according to the protocol $\mathcal{P}$. $\mathcal{F}$ may use this query to perform active attacks by modifying and inserting the messages of the protocol. A query **Send**($\Pi_A^s$, Start) initializes the protocol, and thus the adversary receives the flow that $A$ should send out to $B$.
- **Reveal**($\Pi_{A,B}^s$): This query models *known key attacks* in the real system. $\mathcal{F}$ is allowed to expose an old session key that has been previously accepted. $\Pi_{A,B}^s$, upon receiving the query and if it has accepted and holds some session key, will send this session key back to $\mathcal{F}$.
- **Corrupt**($i$): This query models exposure of the long-term secret key held by $i \in \{A, B\}$ to the adversary $\mathcal{F}$. In the real scenarios, an insider cooperating with the adversary or an insider who has been completely compromised by the adversary are possible modelled by this query.
- **Test**($\Pi_{A,B}^s$): This query is the only oracle query that does not corresponding to any of $\mathcal{F}$'s abilities. This query is used to define the advantage of $\mathcal{F}$. When $\mathcal{F}$ asks this query to an instance $\Pi_{A,B}^s$, $\mathcal{F}$ is given either the actual session key or a session key drawn randomly from the session key distribution, according to a random bit $b \in \{0, 1\}$. Note that the **Test** query can be asked at most once by the adversary.

### 2.2 Security Notions

**Freshness.** The notion of freshness is used to identify the session keys about which $\mathcal{F}$ ought not to know anything because $\mathcal{F}$ has not revealed any oracles that have accepted the key and has not corrupted $i \in \{A, B\}$. An oracle $\Pi_{A,B}^s$ is said *fresh* if:

- $\Pi_{A,B}^s$ has accepted a session key $sk$ and $\Pi_{A,B}^s$ has not been asked for a **Reveal** query,
- No **Corrupt** query has been asked before a query of the form **Send**($\Pi_A^s, *$) or **Send**($\Pi_B^s, *$).

**Definitions of Security.** The security of the protocol $\mathcal{P}$ is defined using the following game, played between an adversary $\mathcal{F}$ and a collection of $\Pi_{A,B}^s$ oracles for players $A, B$ and $s \in \mathbb{N}$.

- In the initialization phase, each player $i \in \{A, B\}$ is assigned a long-term key related to the security parameter.
- In the running phase, an adversary $\mathcal{F}$ may ask some queries and get back the answers from the corresponding oracles.
- At some point, the adversary $\mathcal{F}$ asks a **Test** query to a *fresh* oracle, and outputs its guess $b'$ for the bit $b$ involved in the **Test** query.

Success of $\mathcal{F}$ in the game is quantified in terms of $\mathcal{F}$'s advantage in distinguishing whether $\mathcal{F}$ receives a real session key or a random value, i.e., its ability guessing $b$. We define $\mathcal{F}$'s advantage as

$$\mathbf{Adv}_{\mathcal{P}}^{aka}(\mathcal{F}) = |2 \times \Pr[b = b'] - 1|$$

where the probability space is over all the random coins of the adversary and all the oracles. We say that the protocol $\mathcal{P}$ is secure if $\mathbf{Adv}_{\mathcal{P}}^{aka}(\mathcal{F})$ is negligible in the security parameter.

## 3 Preliminaries

### 3.1 Bilinear Pairings

In recent years, the bilinear pairings have been found various applications in cryptography and have been used to construct some new cryptographic primitives [1, 4].

Let $\mathbb{G}_1$ be a cyclic additive group and $\mathbb{G}_2$ be a cyclic multiplicative group of the same prime order $q$. We assume that the discrete logarithm problems in both $\mathbb{G}_1$ and $\mathbb{G}_2$ are hard. A bilinear pairing is a map $e : \mathbb{G}_1 \times \mathbb{G}_1 \rightarrow \mathbb{G}_2$ which satisfies the following properties:

1. Bilinear: For any $P, Q \in \mathbb{G}_1$ and $a, b \in \mathbb{Z}_q^*$, we have $e(aP, bQ) = e(P, Q)^{ab}$.
2. Non-degenerate: There exists $P \in \mathbb{G}_1$ and $Q \in \mathbb{G}_1$ such that $e(P, Q) \neq 1$.
3. Computable: There exists an efficient algorithm to compute $e(P, Q)$ for all $P, Q \in \mathbb{G}_1$.

From the literature [1], we note that such a bilinear pairing may be realized using the modified Weil pairing associated with supersingular elliptic curves.

### 3.2 Computational Diffie-Hellman Assumption

The Computational Diffie-Hellman (CDH) problem in $\mathbb{G}_1$ is to compute $abP \in \mathbb{G}_1$ when given $P$, $aP$ and $bP$ for some $a, b \in \mathbb{Z}_q^*$.

A $(\tau, \epsilon)$-CDH adversary in $\mathbb{G}_1$ is a probabilistic machine $\Phi$ running in time $\tau$ such that

$$\mathbf{Succ}_{\mathbb{G}_1}^{cdh}(\Phi) = \Pr[\Phi(P, aP, bP) = abP] \geq \epsilon$$

where the probability is taken over the random values $a$ and $b$. The CDH problem is $(\tau, \epsilon)$-intractable if there is no $(\tau, \epsilon)$-adversary in $\mathbb{G}_1$. The CDH assumption states that is the case for all polynomial $\tau$ and any non-negligible $\epsilon$.

## 4 Our Proposed Protocol

In this section, we introduce our new two-party authentication key agreement protocol from bilinear pairings. The protocol is composed of two phases: *protocol initialization* and *protocol running*. We describe each of them in turn.

### 4.1 Protocol Initialization

As described in section 3.1, $\mathbb{G}_1$, $\mathbb{G}_2$ are two groups of the same prime order $q$, where $|q| = k_1$, and $e : \mathbb{G}_1 \times \mathbb{G}_1 \to \mathbb{G}_2$ is an admissible bilinear map in the system. Let $P$ be a generator of $\mathbb{G}_1$ and $H_1, H_2$ and $H_3$ be three secure hash functions, where $H_1 : \{0,1\}^* \to \mathbb{G}_1$, $H_2 : \{0,1\}^* \to \mathbb{G}_1$ and $H_3 : \{0,1\}^* \to \{0,1\}^{k_2}$. Here $k_1, k_2$ are two secure parameters.

The player $A$ chooses a random $x_A \in \mathbb{Z}_q^*$ as her private key, and computes the corresponding public key $Y_A = x_A P$. Similarly, the player $B$ also chooses a random $x_B \in \mathbb{Z}_q^*$ as his private key, and computes his public key $Y_B = x_B P$.

### 4.2 Protocol Running

When $A$ and $B$ want to establish a session key, they execute the following protocol as shown in Figure 1:

| $\boldsymbol{A}$ | | $\boldsymbol{B}$ |
|---|---|---|
| $(x_A, Y_A = x_A P)$ | | $(x_B, Y_B = x_B P)$ |
| $a \xleftarrow{R} \mathbb{Z}_q^*;\ X_1 = aP$ | | |
| $h_1 = H_1(X_1 \Vert ID_A \Vert ID_B)$ | | |
| $Y_1 = x_A h_1$ | $\xrightarrow{ID_A, (X_1, Y_1)}$ | |
| | | $h_1 = H_1(X_1 \Vert ID_A \Vert ID_B)$ |
| | | $e(Y_A, h_1) \stackrel{?}{=} e(P, Y_1)$ |
| | | $b \xleftarrow{R} \mathbb{Z}_q^*;\ X_2 = bP$ |
| | | $Z = bX_1 = abP$ |
| | | $h_2 = H_2(Z \Vert X_1 \Vert X_2 \Vert ID_A \Vert ID_B)$ |
| | $\xleftarrow{ID_B, (X_2, Y_2)}$ | $Y_2 = x_B h_2$ |
| $Z = aX_2 = abP$ | | |
| $h_2 = H_2(Z \Vert X_1 \Vert X_2 \Vert ID_A \Vert ID_B)$ | | $sk = H_3(Z \Vert X_1 \Vert X_2 \Vert ID_A \Vert ID_B)$ |
| $e(Y_B, h_2) \stackrel{?}{=} e(P, Y_2)$ | | |
| $sk = H_3(Z \Vert X_1 \Vert X_2 \Vert ID_A \Vert ID_B)$ | | |

**Fig. 1.** Proposed two-party authenticated key agreement protocol

1. $A$ picks a random number $a \in_R Z_q^*$, computes $X_1, h_1, Y_1$, where $X_1 = aP$, $h_1 = H_1(X_1 \Vert ID_A \Vert ID_B)$ and $Y_1 = x_A h_1$. Here $ID_A$, $ID_B$ are the identities of $A$, $B$ and $\Vert$ is the catenation symbol. $A$ then sends $\langle ID_A, X_1, Y_1 \rangle$ to $B$.
2. Upon receiving $\langle ID_A, X_1, Y_1 \rangle$, $B$ computes $h_1 = H_1(X_1 \Vert ID_A \Vert ID_B)$ and checks whether $e(Y_A, h_1) = e(P, Y_1)$. If it is not true, $B$ terminates the protocol. Otherwise, $B$ picks a random number $b \in_R Z_q^*$, and computes $X_2, Z, h_2$ and $Y_2$, where $X_2 = bP$, $Z = bX_1 = abP$, $h_2 = H_2(Z \Vert X_1 \Vert X_2 \Vert ID_A \Vert ID_B)$ and $Y_2 = x_B h_2$. Finally, $B$ sends $\langle ID_B, X_2, Y_2 \rangle$ to $A$, and computes the session key $sk = H_3(Z \Vert X_1 \Vert X_2 \Vert ID_A \Vert ID_B)$.

3. When $A$ receives $\langle ID_B, X_2, Y_2 \rangle$, she computes $Z = aX_2 = abP$ and $h_2 = H_2(Z \| X_1 \| X_2 \| ID_A \| ID_B)$. Then she checks whether $e(Y_B, h_2) = e(P, Y_2)$. If it is not true, $A$ also aborts the protocol. Otherwise, $A$ computes the session key $sk = H_3(Z \| X_1 \| X_2 \| ID_A \| ID_B)$.

*Correctness.* In an honest execution of the proposed protocol in Figure 1, we have the Diffie-Hellman secret value $aX_2 = bX_1 = Z = abP$, Hence the correctness follows.

*Efficiency.* In the proposed protocol, the hash functions $H_1, H_2$ are Map-To-Point operations, which require many computations. However, with several efficient algorithms available for pairings [3, 5] and some off-line computations in the protocol, the efficiency of the protocol is acceptable.

## 5 Security

In this section, we prove that our proposed two-party authenticated key agreement protocol is secure in the random oracle model [8] as long as the CDH problem is assumed hard in $\mathbb{G}_1$. Before doing that, we first show that the transcripts of the player $i$, $i \in \{A, B\}$, is unforgeable.

**Lemma 1.** *Assume that the hash function $H_1$ is a random oracle. Let $\mathcal{F}_s$ be an adversary which can, with success probability $\epsilon$, forge a valid transcript of the player $A$ within a time $\tau$, after $q_h$ and $q_s$ to the hash oracle $H_1$ and **Send** oracle, respectively. Then, there exists an attacker $\Phi_s$ that solves the CDH problem with another probability $\epsilon'$ within time $\tau'$, where*

$$\epsilon' \geq \frac{1}{(q_s + 1)\exp(1)} \cdot \epsilon, \quad \tau' \leq \tau + (q_h + q_s + 1) \cdot t_{pm}$$

*with* $\exp(1) \approx 2.17\ldots$ *the Napierian logarithm base and $t_{pm}$ the time for a point scalar multiplication evaluation in $\mathbb{G}_1$.*

*Proof.* Initially, $\Phi_s$ is given an instance $(P, xP, yP) \in \mathbb{G}_1$ of the CDH problem, where $x, y \in \mathbb{Z}_q^*$, and its goal is to compute $xyP \in \mathbb{G}_1$. $\Phi_s$ then runs $\mathcal{F}_s$ as a subroutine and simulates its attack environment. First, $\Phi_s$ sets $Y_A = xP$, the public key of the player $A$ and gives it to $\mathcal{F}_s$.

Then, $\Phi_s$ will respond $\mathcal{F}_s$'s hash oracle $H_1$ and **Send** oracle queries. To avoid collision and consistently respond to these queries, a hash list $\Lambda_{\mathcal{H}}$, which is initially empty, will maintained by $\Phi_s$. Concretely, $\Phi_s$ interacts with $\mathcal{F}_s$ as follows:

**$\mathbf{H_1}$-query.** At any time, $\mathcal{F}_s$ provides a message $m$ for $H_1$ oracle query. To respond it, $\Phi_s$ selects a random number $r \in \mathbb{Z}_q^*$ and then

- with probability $\alpha$, computes $rP \in \mathbb{G}_1$, adds $(m, r, rP)$ to $\Lambda_{\mathcal{H}}$, and responds to $\mathcal{F}_s$ with $H_1(m) = rP$, where $\alpha$ is a fixed probability determined later [9];
- with probability $1 - \alpha$, computes $ryP \in \mathbb{G}_1$, adds $(m, r, ryP)$ to $\Lambda_{\mathcal{H}}$, and responds to $\mathcal{F}_s$ with $H_1(m) = ryP$.

Note that the form of the message $m$ is $X_1 \| ID_A \| ID_B$ here.
**Send-query.** When $\mathcal{F}_s$ makes a $\mathbf{Send}(\Pi_A^s, m)$ query, which has been preceded by an $H_1$ query. $\Phi_s$ looks up $\Lambda_{\mathcal{H}}$.

- If $H_1(m) = rP$, with probability $\alpha$, $\Phi_s$ computes $Y = rxP$ and sets $Y_1 = Y$ and returns $\langle ID_A, (X_1, Y_1) \rangle$ to $\mathcal{F}_s$. Obviously, the simulation works correctly since $\mathcal{F}_s$, without knowing the private key of $A$, can not distinguish whether any transcript $\langle ID_A, (X_1, Y_1) \rangle$ is valid or not.
- If $H_1(m) = rbP$, with probability $1-\alpha$, $\Phi_s$ terminates the game and admits failure.

Eventually, $\mathcal{F}_s$ outputs a valid transcript $\langle ID_A, (X^\star, Y^\star) \rangle$. As we assume that the hash value $H_1(m)$ of $m$ has been asked and existed in $\Lambda_{\mathcal{H}}$. In the found entry in $\Lambda_{\mathcal{H}}$,

- If $H_1(m) = rP$, with probability $\alpha$, $\Phi_s$ terminates the game and admits failure.
- If $H_1(m) = ryP$, with probability $1-\alpha$, $\Phi_s$ obtains the challenged $xyP$ by computing $r^{-1}Y^\star = r^{-1}rxyP = xyP$, since we have $Y^\star = rxyP$ and know the value of $r$.

Based upon the analysis above, if the game does't terminate, $\Phi_s$ resolves the CDH problem with probability at least $\epsilon'$, where $\epsilon' = \alpha^{q_s}(1-\alpha)\epsilon$. Since the maximum value of $\alpha^{q_s}(1-\alpha)\epsilon$ is $\frac{1}{q_s+1} \cdot (\frac{1}{1+\frac{1}{q_s}})^{q_s}$, where $\alpha = \frac{q_s}{q_s+1}$, we will have $\epsilon' = \frac{1}{q_s+1} \cdot (\frac{1}{1+\frac{1}{q_s}})^{q_s} \cdot \epsilon$. And for the enough large $q_s$, $(\frac{1}{1+\frac{1}{q_s}})^{q_s} \approx \frac{1}{\exp(1)}$. Therefore, $\epsilon' \geq \frac{1}{(q_s+1)\exp(1)} \cdot \epsilon$, which is our desired. □

**Lemma 2.** *Assume that the hash function $H_2$ is a random oracle. Let $\mathcal{F}_s$ be an adversary which can, with success probability $\epsilon$, forge a valid transcript of the player $B$ within a time $\tau$, after $q_h$ and $q_s$ to the hash oracle $H_2$ and **Send** oracle, respectively. Then, there exists an attacker $\Phi_s$ that solves the CDH problem with another probability $\epsilon'$ within time $\tau'$, where*

$$\epsilon' \geq \frac{1}{(q_s+1)\exp(1)} \cdot \epsilon, \quad \tau' \leq \tau + (q_h + q_s + 1) \cdot t_{pm}$$

*with $\exp(1) \approx 2.17\ldots$ the Napierian logarithm base and $t_{pm}$ the time for a point scalar multiplication evaluation in $\mathbb{G}_1$.*

*Proof.* The proof is similar to the proof of Lemma 1 and therefore it is omitted. Here we should note that, when $\mathcal{F}_s$ makes the $H_2$ and **Send** oracles, the message $m$ in $H_2(m)$ and $\mathbf{Send}(\Pi_B^s, m)$ has the form of $Z \| X_1 \| X_2 \| ID_A \| ID_B$, where $X_2 = bP$ and $Z = bX_1$ for some $b \in \mathbb{Z}_q^*$. □

We denote $\mathbf{Succ}_{\mathsf{SIG}}^{cma}(\tau')$ the maximum success probability of any adversary running in time $\tau'$ to forge the transcript of the player $i$, $i \in \{A, B\}$. Then, we

have the advantage $\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_s)$ of the adversary $\mathcal{F}_s$ to break the protocol by forging the transcript of $A$ and $B$ is bounded by

$$\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_s) \leq \mathbf{Succ}^{cma}_{\mathsf{SIG},\mathcal{F}_s \to A}(\tau') + \mathbf{Succ}^{cma}_{\mathsf{SIG},\mathcal{F}_s \to B}(\tau') \leq 2 \cdot \mathbf{Succ}^{cma}_{\mathsf{SIG}}(\tau')$$

By Lemma 1 and Lemma 2, the advantage $\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_s)$ is negligible.

Next, we consider the case in which an adversary $\mathcal{F}_p$ breaks the protocol without altering the transcripts.

**Lemma 3.** *Assume that the hash functions $H_1$, $H_2$ and $H_3$ are random oracles. Let $\mathcal{F}_p$ be an adversary which can break the proposed protocol without altering the transcripts, within a time $\tau$, after making several oracles' queries defined in section 2.1. Then, we have*

$$\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_p) \leq 2q_s \cdot \mathbf{Succ}^{cdh}_{\mathbb{G}_1}(\tau')$$

*where $\tau'$ is the total running time and $q_s$ is the total number of session instances $\Pi^1_{A,B}, \Pi^2_{A,B}, \cdots, \Pi^{q_s}_{A,B}$.*

*Proof.* Since the adversary $\mathcal{F}_p$ can, with non-negligible advantage, break the proposed protocol, using $\mathcal{F}_p$, we can construct another attacker $\Phi_p$ to solve the CDH problem in $\mathbb{G}_1$.

First, $\Phi_p$ is given an instance of the CDH problem $(P, xP, yP)$, where $x, y \in \mathbb{Z}^*_q$, and its goal is to compute $xyP \in \mathbb{G}_1$. Then, $\Phi_p$ runs $\mathcal{F}_p$ as a subroutine and simulates its attack environment.

For each player $i \in \{A, B\}$, $\Phi_p$ chooses $x_i \in \mathbb{Z}^*_q$, and creates a public key as $Y_i = x_i P$. Then, $\Phi_p$ gives the public keys $Y_A$, $Y_B$ to $\mathcal{F}_p$ and interacts with him.

In the game below, $\Phi_p$ simulates the hash oracles $H_1$, $H_2$ and $H_3$, as usual by maintaining hash list $\Lambda_{\mathcal{H}_1}$, $\Lambda_{\mathcal{H}_2}$ and $\Lambda_{\mathcal{H}_3}$ for avoiding collision and consistently response. $\Phi_p$ also simulates all the instances, as the real players would do, for the **Send**, **Execute**, **Reveal**, **Corrupt** and **Test** queries. Without loss of generality, we assume that all queries are distinct, that is, $\mathcal{F}_p$ doesn't ask queries on a same message more than once. To make use of the advantage of $\mathcal{F}_p$, $\Phi_p$ guesses $\beta$ such that $\mathcal{F}_p$ asks its **Test** query in the $\beta$-th session.

**$\mathbf{H_1}$-query.** When $\mathcal{F}_p$ makes a hash query $H_1(m)$ such that a record $\langle m, r_1, r_1 P\rangle$ appears in $\Lambda_{\mathcal{H}_1}$, $\Phi_p$ answers with $r_1 P$. Otherwise, $\Phi_p$ chooses a random $r_1 \in \mathbb{Z}^*_q$, adds $\langle m, r_1, r_1 P\rangle$ to $\Lambda_{\mathcal{H}_1}$ and returns $r_1 P$ to $\mathcal{F}_p$.

**$\mathbf{H_2}$-query.** When $\mathcal{F}_p$ makes a hash query $H_2(m)$ such that a record $\langle m, r_2, r_2 P\rangle$ appears in $\Lambda_{\mathcal{H}_2}$, $\Phi_p$ answers with $r_2 P$. Otherwise, $\Phi_p$ chooses a random $r_2 \in \mathbb{Z}^*_q$, adds $\langle m, r_2, r_2 P\rangle$ to $\Lambda_{\mathcal{H}_2}$ and returns $r_2 P$ to $\mathcal{F}_p$.

**$\mathbf{H_3}$-query.** When $\mathcal{F}_p$ makes a hash query $H_3(m)$ such that a record $\langle m, r_3\rangle$ appears in $\Lambda_{\mathcal{H}_3}$, $\Phi_p$ answers with $r_3$. Otherwise, $\Phi_p$ chooses a random $r_3 \in \{0,1\}^{k_2}$, adds $\langle m, r_3\rangle$ to $\Lambda_{\mathcal{H}_3}$ and returns $r_3$ to $\mathcal{F}_p$.

**Send-query.** We classifies **Send-query** into three types as follows:

- **Send**$(\Pi^s_A, \mathsf{Start})$. When $\mathcal{F}_p$ makes a **Send**$(\Pi^s_A, \mathsf{Start})$ query,

  - if the query is in the $\beta$-th session, $\Phi_p$ chooses a random $r_1 \in \mathbb{Z}_q^*$, computes $X_1 = xP$, $Y_1 = x_A r_1 P$ and returns $ID_A$ and $(X_1, Y_1)$ to $\mathcal{F}_p$.
  - otherwise, $\Phi_p$ chooses two random numbers $a, r_1 \in \mathbb{Z}_q^*$, computes $X_1 = aP$, $Y_1 = x_A r_1 P$ and returns $ID_A$ and $(X_1, Y_1)$ to $\mathcal{F}_p$. $\Phi_p$ also adds $\langle m, r_1, r_1 P\rangle$ to $\Lambda_{\mathcal{H}_1}$, where $m = X_1 \| ID_A \| ID_B$. The instance $\Pi_A^s$ then goes to an expecting state.

– **Send**$(\Pi_B^s, (ID_A, X_1, Y_1))$. When $\mathcal{F}_p$ makes a **Send**$(\Pi_B^s, (ID_A, X_1, Y_1))$ query,

  - if the query is in the $\beta$-th session, $\Phi_p$ chooses a random $r_2 \in \mathbb{Z}_q^*$, computes $X_2 = yP$, $Y_2 = x_B r_2 P$ and returns $ID_B$ and $(X_2, Y_2)$ to $\mathcal{F}_p$.
  - otherwise, after checking $(X_1, Y_1)$, $\Phi_p$ chooses two random numbers $b, r_2 \in \mathbb{Z}_q^*$, computes $X_2 = bP$, $Z = bX_1 = abP$ and $Y_2 = x_B r_2 P$ and returns $ID_B$ and $(X_2, Y_2)$ to $\mathcal{F}_p$. $\Phi_p$ also adds $\langle m, r_2, r_2 P\rangle$ to $\Lambda_{\mathcal{H}_2}$, where $m = Z \| X_1 \| X_2 \| ID_A \| ID_B$. Finally, $\Phi_p$ chooses a random $r_3 \in \{0,1\}^{k_2}$ as the session key $sk$ and adds $\langle m, r_3\rangle$ to $\Lambda_{\mathcal{H}_3}$.

– **Send**$(\Pi_A^s, (ID_B, X_2, Y_2))$. When $\mathcal{F}_p$ makes a **Send**$(\Pi_A^s, (ID_B, X_2, Y_2))$ query,

  - if the query is in the $\beta$-th session, $\Phi_p$ does nothing.
  - otherwise, $\Phi_p$ checks the validity of the transcript $(X_2, Y_2)$.

**Execute-query.** When $\mathcal{F}_p$ makes an **Execute**$(A, B)$, then $\Phi_p$ returns the transcript $((ID_A, X_1, Y_1), (ID_B, X_2, Y_2))$ using the above successive simulation of **Send** queries.

**Reveal-query.** When $\mathcal{F}_p$ makes a **Reveal**$(\Pi_{A,B}^s)$ query, if $\Pi_{A,B}^s$ is accepted, $\Phi_p$ returns the session key $sk$ to $\mathcal{F}_p$.

**Corrupt-query.** When $\mathcal{F}_p$ makes a **Corrupt**$(i)$ query on the player $i$, $i \in \{A, B\}$, $\Phi_p$ returns the private key $x_i$ to $\mathcal{F}_p$.

**Test-query.** When $\mathcal{F}_p$ makes a **Test** query,

– if the query is asked in the $\beta$-th session, $\Phi_p$ flips a coin $b$. If $b = 1$, $\Phi_p$ returns the value of the session key $sk$, otherwise he returns a random value drawn from $\{0,1\}^{k_2}$.
– otherwise, $\Phi_p$ terminates the protocol and reports failure.

Let $\mathsf{E}$ the event that $\Phi_p$ guesses the correct the $\beta$-th session that $\mathcal{F}_p$ wants to make the **Test** query from total $q_s$ session instances $\Pi_{A,B}^s$. Thus we have $\Pr[\mathsf{E}] \geq \frac{1}{q_s}$.

If $\mathcal{F}_p$ does not detect any inconsistencies in $\Phi_p$'s responses and guesses the correct value of $b$, i.e. $b = b'$, which means that $\mathcal{F}_p$ knows the session key $sk$ corresponded to the $\beta$-th session query. Then, he must have issued a query for $H_3(xyP \| X_1 \| X_2 \| ID_A \| ID_B)$ with advantage $\frac{1}{2}\mathbf{Adv}_{\mathcal{P}}^{aka}(\mathcal{F}_p)$, since $\frac{1}{2}\mathbf{Adv}_{\mathcal{P}}^{aka}(\mathcal{F}_p) = \Pr[b = b'] - \frac{1}{2}$. Therefore, by looking up the entry $\langle m, r_3\rangle$ in $\Lambda_{\mathcal{H}_3}$ and checking them by the algorithm Solve-CDH below, $\Phi_p$ can get the Diffie-Hellman secret value $Z = xyP$ with probability at least $\frac{1}{2}\mathbf{Adv}_{\mathcal{P}}^{aka}(\mathcal{F}_p)$ when the

event $\mathsf{E}$ occurs.

**Algorithm:** Solve-CDH$(\Lambda_{\mathcal{H}_3}, xP, yP)$
**for** $i := 1$ **to** $|\Lambda_{\mathcal{H}_3}|$
$\langle m, r_3\rangle \leftarrow \Lambda_{\mathcal{H}_3}$;
$Z\|X_1\|X_2\|ID_A\|ID_B \leftarrow m$;
**if** $X_1 = xP$ **and** $X_2 = yP$ **and** $e(X_1, X_2) = e(Z, P)$
**then return** $Z = xyP$;

Then, we have

$$\mathbf{Succ}^{cdh}_{\mathbb{G}_1}(\tau') = \Pr[\mathsf{E}] \cdot \frac{1}{2}\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_p) \geq \frac{1}{q_s} \cdot \frac{1}{2}\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_p)$$

Therefore,

$$\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_p) \leq 2q_s \times \mathbf{Succ}^{cdh}_{\mathbb{G}_1}(\tau')$$

where $\tau'$ is the total running time, which includes $\mathcal{F}_p$'s running time $\tau$ and other time costed in the game. □

To break the proposed protocol $\mathcal{P}$, an active adversary $\mathcal{F}$ can get the advantage $\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F})$ by (i) forging authentication transcripts of the player $A$ and $B$; (ii) breaking the protocol without altering the transcript. Therefore, based upon three Lemmas above, we have

$$\mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}) = \mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_s) + \mathbf{Adv}^{aka}_{\mathcal{P}}(\mathcal{F}_p) \leq 2 \cdot \mathbf{Succ}^{cma}_{\mathsf{SIG}}(\tau') + 2q_s \cdot \mathbf{Succ}^{cdh}_{\mathbb{G}_1}(\tau').$$

As a consequence, we can reach the following security result

**Theorem 1.** *Our proposed pairing-based two-party authenticated key agreement protocol is secure, given the CDH assumption and the hash functions are assumed random oracles.* □

## 6 Conclusions

In this paper, we have presented a new pairing-based two-party authenticated key agreement protocol, which could provide the full forward secrecy. That is, compromise of private keys of both parties does not appear to allow an attacker to recover any past session keys using transcripts. Within the specific Bellare-Rogaway model, our protocol has been strictly proved to be secure in the random oracle model under the CDH assumption.
