ALPHACERTIFIED: CERTIFYING SOLUTIONS TO POLYNOMIAL SYSTEMS

JONATHAN D. HAUENSTEIN AND FRANK SOTTILE

Abstract. Smale's α-theory uses estimates related to the convergence of Newton's method to give criteria implying that Newton iterations will converge quadratically to solutions to a square polynomial system. The program **alphaCertified** implements algorithms based on α-theory to certify solutions to polynomial systems using both exact rational arithmetic and arbitrary precision floating point arithmetic. It also implements an algorithm to certify whether a given point corresponds to a real solution to a real polynomial system, as well as algorithms to heuristically validate solutions to overdetermined systems. Examples are presented to demonstrate the algorithms.

Introduction

Current implementations of numerical homotopy algorithms [1, 31, 37] such as PHCpack [40], HOM4PS [26], Bertini [4], and NAG4M2 [27] routinely and reliably solve systems of polynomial equations with dozens of variables having thousands of solutions. Here, 'solve' means 'compute numerical approximations to solutions.' In each of these software packages, the solutions are validated heuristically—often by monitoring iterations of Newton's method. This works well in practice, giving solutions that are acceptable in most applications. However, a well-known shortcoming of numerical methods for computing approximate solutions to systems of polynomials is that the output is not certified. This restricts their use in some applications, including those in pure mathematics. The program **alphaCertified** is intended to remedy this shortcoming.

In the 1980's, Smale [35] and others investigated the convergence of Newton's method, developing what has come to be called α-theory [9, Ch. 8]. This refers to a computable positive constant $\alpha(f,x)$ that depends upon a system $f\colon \mathbb{C}^n \to \mathbb{C}^n$ of polynomials and a point $x \in \mathbb{C}^n$ such that, if

$$\alpha(f,x) \;<\; \frac{13-3\sqrt{17}}{4} \;\approx\; 0.157671\,,$$

then iterations of Newton's method starting at x will converge quadratically to a solution to f, which is a point $\xi \in \mathbb{C}^n$ with $f(\xi)=0$. In principle, Smale's α-theory provides certificates for validating numerical computations with polynomials.

Current implementations of numerical homotopy algorithms do not incorporate α-theory to certify their output, or to certify their path-tracking. Besides the complexity of applying the theory, certified tracking was expected to slow the computation to the point of infeasibility. In 2003, Malajovich [29] released the most recent version of his Polynomial System Solver which used α-theory to certify toric path-tracking algorithms. Recently, Beltrán and Leykin [8] have shown how to use α-theory to certify path-tracking, and hence the output of numerical homotopy algorithms. While they demonstrate that certification can dramatically affect the speed of computation, this is an important development, as certified path-tracking is necessary for applications such as numerical irreducible decomposition [36] or computing Galois groups [28].

We describe a program, **alphaCertified**, that implements elements of α-theory to certify numerical solutions to systems of polynomial equations. As it may be used to certify the output of numerical computation, it avoids some conceptual and practical bottlenecks of certified tracking, while delivering some of its benefits. More specifically, given a square polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$, **alphaCertified** uses Smale's α-theory to answer the following three questions for a finite set of points $X \subset \mathbb{C}^n$:

(1) From which points of X will Newton's method converge quadratically to some solution to f?
(2) From which points of X will Newton's method converge quadratically to distinct solutions to f?
(3) If Newton's method defines a real map, from which points of X will Newton's method converge quadratically to real solutions to f?

Often, a sharp upper bound B on the number of roots to a square polynomial system f is known. In this case, given a set of B points, **alphaCertified** can be used to certify that iterations of Newton's method starting from each point in the set converge quadratically to some solution to f and that these solutions are distinct. Such a certificate guarantees that each of the B roots of f can be approximated to arbitrary accuracy using Newton's method. Moreover, **alphaCertified** can certify how many of the B solutions to f are real when f is a real map.

A polynomial system $f : \mathbb{C}^n \to \mathbb{C}^N$ is overdetermined if $N > n$, that is, if the number of variables is less than the number of polynomials. Dedieu and Shub [12] studied Newton's method for overdetermined polynomial systems to determine conditions which guarantee quadratic convergence of its iterations. Unlike square systems, the fixed points of this overdetermined Newton's method need not be solutions. For example, $x = 1$ is a fixed point of Newton's method applied to $f(x) = \begin{bmatrix} x \\ x-2 \end{bmatrix}$.

The program **alphaCertified** implements a heuristic validation of solutions to overdetermined systems. Given a finite set $X \subset \mathbb{C}^n$ and an overdetermined system, it generates two or more random square subsystems, answers the three questions above for each, and compares the results. In particular, given $\delta > 0$, it can certify that, for a given approximate solution to two or more random subsystems, the associated solutions all lie within a distance δ of each other.

In Section 1, we review the concepts of α-theory utilized by **alphaCertified**. Section 2 presents the algorithms for square polynomial systems while Section 3 describes our approach to overdetermined polynomial systems. Implementation details regarding **alphaCertified** are presented in Section 4 with examples presented in Section 5 in which we verify some computational results in kinematics and generate evidence for possible conjectures in enumerative real algebraic geometry.

1. Smale's α-theory

We summarize key points of Smale's α-theory for square polynomial systems that are utilized by **alphaCertified**. More details may be found in [9, Ch. 8].

Let $f : \mathbb{C}^n \to \mathbb{C}^n$ be a system of n polynomials in n variables with common zeroes $\mathcal{V}(f) := \{\xi \in \mathbb{C}^n \mid f(\xi) = 0\}$, and let $Df(x)$ be the Jacobian matrix of the system f at x. Consider the map $N_f : \mathbb{C}^n \to \mathbb{C}^n$ defined by

$$N_f(x) \;:=\; \begin{cases} x - Df(x)^{-1}f(x) & \text{if } Df(x) \text{ is invertible,} \\ x & \text{otherwise.} \end{cases}$$

The point $N_f(x)$ is called the *Newton iteration of f starting at x*. For $k \in \mathbb{N}$, let

$$N_f^k(x) \;:=\; \underbrace{N_f \circ \cdots \circ N_f(x)}_{k \text{ times}}$$

be the k^{th} Newton iteration of f starting at x.

Definition 1. Let $f : \mathbb{C}^n \to \mathbb{C}^n$ be a polynomial system. A point $x \in \mathbb{C}^n$ is an *approximate solution* to f with *associated solution* $\xi \in \mathcal{V}(f)$ if, for every $k \in \mathbb{N}$,

$$\|N_f^k(x) - \xi\| \;\le\; \left(\frac{1}{2}\right)^{2^k-1} \|x - \xi\|\,. \tag{1}$$

That is, the sequence $\{N_f^k(x) \mid k \in \mathbb{N}\}$ *converges quadratically* to ξ. Here, $\|\cdot\|$ is the usual hermitian norm on $\mathbb{C}^n$, namely $\|(x_1, \ldots, x_n)\| = (|x_1|^2 + \cdots + |x_n|^2)^{1/2}$.

Smale's α-theory describes conditions certifying that a given point x is an approximate solution to f. It is based on the constants $\alpha(f,x)$, $\beta(f,x)$, and $\gamma(f,x)$. If $Df(x)$ is invertible, these constants are

$$\begin{aligned} \alpha(f,x) &:= \beta(f,x)\gamma(f,x)\,, \\ \beta(f,x) &:= \|x - N_f(x)\| \;=\; \|Df(x)^{-1}f(x)\|\,, \qquad \text{and} \\ \gamma(f,x) &:= \sup_{k\ge 2} \left\| \frac{Df(x)^{-1}D^k f(x)}{k!} \right\|^{\frac{1}{k-1}}. \end{aligned} \tag{2}$$

If $x \in \mathcal{V}(f)$ is such that $Df(x)$ is not invertible, then we define $\alpha(f,x) := \beta(f,x) := 0$ and $\gamma(f,x) := \infty$. Otherwise, if $x \notin \mathcal{V}(f)$ and $Df(x)$ is not invertible, the we define $\alpha(f,x) := \beta(f,x) := \gamma(f,x) := \infty$.

We explain the formula (2) for $\gamma(f,x)$. The k^{th} derivative $D^k f(x)$ [25, Chap. 5] to f is the symmetric tensor whose components are the partial derivatives of f of order k. It

is a linear map from the k-fold symmetric power $S^k\mathbb{C}^n$ of $\mathbb{C}^n$ to $\mathbb{C}^n$. The norm in (2) is the operator norm of the map $Df(x)^{-1}D^kf(x)\colon S^k\mathbb{C}^n \to \mathbb{C}^n$, defined with respect to the norm on $S^k\mathbb{C}^n$ that is dual to the standard unitarily invariant norm on homogeneous polynomials,

$$\big\|\sum_{|\nu|=d} a_\nu x^\nu\big\|^2 \;:=\; \sum_{|\nu|=d} |a_\nu|^2/\tbinom{d}{\nu}\,,$$

where $\nu = (\nu_1,\ldots,\nu_n)$ is an exponent vector of non-negative integers with $|\nu| = \nu_1+\cdots+\nu_n$ and $x^\nu = x_1^{\nu_1}\cdots x_n^{\nu_n}$, and $\binom{d}{\nu} = \frac{d!}{\nu_1!\cdots\nu_n!}$ is the multinomial coefficient.

The following version of Theorem 2 from page 160 of [9] provides a certificate that a point x is an approximate solution to f.

Theorem 2. *If $f:\mathbb{C}^n\to\mathbb{C}^n$ is a polynomial system and $x\in\mathbb{C}^n$ with*

$$\alpha(f,x) \;<\; \frac{13-3\sqrt{17}}{4} \;\approx\; 0.157671\,,$$

then x is an approximate solution to f. Additionally, $\|x-\xi\|\le 2\beta(f,x)$ where $\xi\in\mathcal{V}(f)$ is the associated solution to x.

Remark 3. If $\alpha(f,x)\ge\frac{1}{4}$, then x may not be an approximate solution to f. For example, for $f(x)=x^2$, if $x\neq 0$, then x is not an approximate solution to f yet $\alpha(f,x)=\frac{1}{4}$.

Theorem 4 and Remark 6 of [9, Ch. 8] provide a robust version of Theorem 2 that is used by **alphaCertified** to certify that two approximate solutions have the same associated solution.

Theorem 4. *Let $f:\mathbb{C}^n\to\mathbb{C}^n$ be a polynomial system, $x\in\mathbb{C}^n$ with $\alpha(f,x)<0.03$ and $\xi\in\mathcal{V}(f)$ the associated solution to x. If $y\in\mathbb{C}^n$ with*

$$\|x-y\| \;<\; \frac{1}{20\gamma(f,x)}\,,$$

then y is an approximate solution to f with associated solution ξ.

1.1. **Bounding higher order derivatives.** The invariant $\gamma(f,x)$, which encodes the behavior of the higher order derivatives of f at x, may be difficult to compute exactly. Nonetheless, it can be bounded above using information about the point x, the polynomial system f, and the first derivatives of f at x.

For a polynomial $g:\mathbb{C}^n\to\mathbb{C}$ of degree d, say $g=\sum_{|\nu|\le d} a_\nu x^\nu$, define

$$\|g\|^2 \;:=\; \sum_{|\nu|\le d} |a_\nu|^2\,\frac{\nu!(d-|\nu|)!}{d!}\,.$$

Then $\|\cdot\|$ is the standard unitarily invariant norm on the homogenization of g. For a polynomial system $f:\mathbb{C}^n\to\mathbb{C}^n$, define

$$\|f\|^2 \;:=\; \sum_{i=1}^n \|f_i\|^2 \qquad \text{where} \qquad f(x) \;=\; \begin{bmatrix} f_1(x)\\ \vdots\\ f_n(x)\end{bmatrix}\,,$$

and for a point $x \in \mathbb{C}^n$, define

$$\|x\|_1^2 \;:=\; 1 + \|x\|^2 \;=\; 1 + \sum_{i=1}^{n} |x_i|^2 \,.$$

Let $\Delta_{(d)}(x)$ be the $n \times n$ diagonal matrix with

$$\Delta_{(d)}(x)_{i,i} \;:=\; d_i \|x\|_1^{d_i - 1} \,,$$

where d_i is the degree of f_i. If $Df(x)$ is invertible, define

$$\mu(f,x) \;:=\; \max\{1, \|f\| \cdot \|Df^{-1}(x)\Delta_{(d)}(x)\|\} \,.$$

The following version of Proposition 3 from §I-3 of [34] provides an upper bound for $\gamma(f,x)$.

Proposition 5. *Let $f : \mathbb{C}^n \to \mathbb{C}^n$ be a polynomial system with $d_i = \deg f_i$ and $D = \max d_i$. If $x \in \mathbb{C}^n$ such that $Df(x)$ is invertible, then*

$$\gamma(f,x) \;\leq\; \frac{\mu(f,x) D^{\frac{3}{2}}}{2\|x\|_1} \,. \tag{3}$$

2. Algorithms for square polynomial systems

Let $f : \mathbb{C}^n \to \mathbb{C}^n$ be a square polynomial system and $X = \{x_1, \ldots, x_k\} \subset \mathbb{C}^n$ be a set of points. We describe the algorithms implemented in **alphaCertified** which answer the three questions posed in the Introduction.

For each $i = 1, \ldots, k$, **alphaCertified** first computes $f(x_i)$ to determine if $x_i \in \mathcal{V}(f)$. If $x_i \notin \mathcal{V}(f)$, **alphaCertified** then determines if $Df(x_i)$ is invertible. If it is, **alphaCertified** computes $\beta(f,x_i)$ and upper bounds for $\alpha(f,x_i)$ and $\gamma(f,x_i)$ using the following algorithm.

Procedure $(\alpha,\beta,\gamma) =$ **ComputeConstants**(f,x)**:**
Input: A square polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$ and a point $x \in \mathbb{C}^n$ such that $Df(x)$ is invertible.
Output: $\alpha := \beta \cdot \gamma$, $\beta := \|Df(x)^{-1} f(x)\|$, and γ, where γ is the upper bound for $\gamma(f,x)$ given in Proposition 5.

The next algorithm uses Theorem 2 to compute a subset Y of X containing points that are certified approximate solutions to f.

Procedure $Y =$ **CertifySolns**(f,X)**:**
Input: A square polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$ and a finite set $X = \{x_1, \ldots, x_k\} \subset \mathbb{C}^n$.
Output: A set $Y \subset X$ of approximate solutions to f.
Begin:
(1) Initialize $Y := \{\}$.
(2) For $j = 1, 2, \ldots, k$, if $f(x_j) = 0$, set $Y := Y \cup \{x_j\}$, otherwise, do the following if $Df(x_j)$ is invertible:
  (a) Set $(\alpha,\beta,\gamma) :=$ **ComputeConstants**(f,x_j).

(b) If $\alpha < \dfrac{13-3\sqrt{17}}{4}$, set $Y := Y \cup \{x_j\}$.

Return: Y

Due to the use of the upper bound for $\gamma(f,x)$ of Proposition 5, $\beta(f,x)$ needs to be smaller to certify that x is an approximate solution to f, and **alphaCertified** may fail to certify a legitimate approximate solution. If **alphaCertified** fails to certify that x is an approximate solution to f, a user may consider retrying after applying a few Newton iterations to x. The software **alphaCertified** does not invoke such an automatic refinement to inputs that it does not certify. The reason is that iterates of a non-linear function (such as a Newton step) may have unpredictable behavior (attracting cycles, chaos) when applied to points that are not in a basin of attraction. However, **alphaCertified** does provide the functionality for the user to accomplish such a process.

Suppose that x is an approximate solution to f with associated solution ξ such that $Df(\xi)$ is invertible. Since x is an approximate solution, $\beta(f, N_f^k(x))$ converges to zero. Since $\gamma(f,x)$ is the supremum of a finite number of continuous functions of y, $\gamma(f, N_f^k(x))$ is bounded. In particular, $\alpha(f, N_f^k(x))$ converges to zero.

Given two approximate solutions x_1 and x_2 to f with associated solutions ξ_1 and ξ_2, respectively, Theorems 2 and 4 can be used to determine if ξ_1 and ξ_2 are equal. In particular, if

$$\|x_1 - x_2\| \;>\; 2(\beta(f,x_1) + \beta(f,x_2))\,,$$

then $\xi_1 \neq \xi_2$ by Theorem 2. If on the other hand we have

$$\alpha(f,x_i) \;<\; 0.03 \qquad \text{and} \qquad \|x_1 - x_2\| \;<\; \frac{1}{20\gamma(f,x_i)}$$

for either $i = 1$ or $i = 2$, then $\xi_1 = \xi_2$ by Theorem 4. This justifies the following algorithm which determines if two approximate solutions correspond to distinct associated solutions.

Procedure $isDistinct = $ **CertifyDistinctSoln**(f, x_1, x_2)**:**
Input: A square polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$ and approximate solutions x_1 and x_2 to f with associated solutions ξ_1 and ξ_2, respectively, such that $Df(\xi_1)$ and $Df(\xi_2)$ are invertible.
Output: A boolean *isDistinct* that describes if $\xi_1 \neq \xi_2$.
Begin: Do the following:
(a) For $i = 1, 2$, set $(\alpha_i, \beta_i, \gamma_i) :=$ **ComputeConstants**(f, x_i).
(b) If $\|x_1 - x_2\| > 2(\beta_1 + \beta_2)$, **Return** True.
(c) If $\alpha_i < 0.03$ and $\|x_1 - x_2\| < \dfrac{1}{20\gamma_i}$, for either $i = 1$ or $i = 2$, **Return** False.
(d) For $i = 1, 2$, update $x_i := N_f(x_i)$ and return to (a).

2.1. **Certifying real solutions.** Theorems 2 and 4 can also be used to determine if a solution associated to an approximate solution is real when the polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$ is real in that $f(\overline{x}) = \overline{f(x)}$, so that $f(\mathbb{R}^n) \subset \mathbb{R}^n$. In this case, N_f defines a real map, $N_f(\overline{x}) = \overline{N_f(x)}$ so $N_f(\mathbb{R}^n) \subset \mathbb{R}^n$. The algorithms to certify real solutions only require that the Newton iteration N_f is real, and not that the polynomial system f is real.

Let x be an approximate solution to f with associated solution ξ. By assumption, $\overline{x}$ is also an approximate solution to f with associated solution $\overline{\xi}$. If

$$\|x - \overline{x}\| \;>\; 2\left(\beta(f,x) + \beta(f,\overline{x})\right) \;=\; 4\beta(f,x)\,,$$

then $\xi \neq \overline{\xi}$ by Theorem 2 since

$$\|\xi - \overline{\xi}\| \;\geq\; \|x - \overline{x}\| - 4\beta(f,x) \;>\; 0\,.$$

Consider the natural projection map $\pi_{\mathbb{R}} : \mathbb{C}^n \to \mathbb{R}^n$ defined by

$$\pi_{\mathbb{R}}(x) \;=\; \frac{x + \overline{x}}{2}\,.$$

Since $\|x - \overline{x}\| = 2\|x - \pi_{\mathbb{R}}(x)\|$, ξ is not real if

$$\|x - \pi_{\mathbb{R}}(x)\| \;>\; 2\beta(f,x)\,. \tag{4}$$

We present both a local and a global approach to show that ξ is real. The local approach is based on Theorem 4 which implies that $\pi_{\mathbb{R}}(x)$ is also an approximate solution to f with associated solution ξ if we have

$$\alpha(f,x) \;<\; 0.03 \qquad \text{and} \qquad \|x - \pi_{\mathbb{R}}(x)\| \;<\; \frac{1}{20\gamma(f,x)}\,. \tag{5}$$

Since N_f is a real map and $\pi_{\mathbb{R}}(x) \in \mathbb{R}^n$, this implies that $\xi \in \mathbb{R}^n$.

We note that this local approach could have been based on showing that x and $\overline{x}$ both correspond to the same solution to yield $\xi = \overline{\xi}$. In particular, if

$$\alpha(f,x) \;<\; 0.03 \qquad \text{and} \qquad \|x - \overline{x}\| \;<\; \frac{1}{20\gamma(f,x)}\,.$$

then Theorem 4 would imply such a statement. However, this is a more restrictive than Condition 5 since $\|x - \overline{x}\| = 2\|x - \pi_{\mathbb{R}}(x)\|$.

When $\alpha(f,x) < \; 0.03$, Conditions 4 and 5 yield closely related statements. Since

$$\frac{5}{3}\beta(f,x) \;=\; \frac{5\alpha(f,x)}{3\gamma(f,x)} \;<\; \frac{5 \cdot 0.03}{3\gamma(f,x)} \;=\; \frac{1}{20\gamma(f,x)}\,,$$

we know that ξ is real if $\|x - \pi_{\mathbb{R}}(x)\| \leq \; \frac{5}{3}\beta(f,x)$ and not real if $\|x - \pi_{\mathbb{R}}(x)\| > 2\beta(f,x)$.

The following algorithm uses the local approach of Conditions 4 and 5 to determine if an approximate solution corresponds to a real associated solution to a polynomial system.

Procedure $isReal = \textbf{CertifyRealSoln}(f,x)$**:**
Input: A square real polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$ such that N_f is a real map and an approximate solution $x \in \mathbb{C}^n$ with associated solution ξ such that $Df(\xi)$ is invertible.
Output: A boolean $isReal$ that describes if $\xi \in \mathbb{R}^n$.
Begin: Do the following:

(a) Set $(\alpha, \beta, \gamma) :=$ **ComputeConstants**(f,x).
(b) If $\|x - \pi_{\mathbb{R}}(x)\| > 2\beta$, **Return** False.
(c) If $\alpha < 0.03$ and $\|x - \pi_{\mathbb{R}}(x)\| < \dfrac{1}{20\gamma}$, **Return** True.
(d) Update $x := N_f(x)$, and return to (a).

For the global approach to certifying real solutions, suppose that we have approximate solutions $x_1, \ldots, x_k$ to f with corresponding associated solutions $\xi_1, \ldots, \xi_k$. Suppose further that $\xi_i \neq \xi_j$ for $i \neq j$. Then, if x_i is an approximate solution such that if $j \neq i$, then $\overline{x_i}$ and x_j correspond to distinct solutions, we conclude that $\xi_i = \overline{\xi_i}$ and so $\xi_i \in \mathbb{R}^n$. Thus this global approach requires *a priori* knowledge about $\mathcal{V}(f)$ as well as an approximate solution corresponding to each solution to f, and consequently can only be applied to certain problems. Nonetheless, it provides an alternative to using a test based on $\gamma(f,x)$.

2.2. **Certification algorithm.** For a given set of points X and a polynomial system f, the following algorithm gives a certified count of the number of approximate solutions to f in X and the number of distinct solutions to f corresponding to points of X.

Procedure $(A, numA, D, numD, R, numR) = \textbf{CertifyCount}(f, X)$**:**
Input: A square polynomial system $f : \mathbb{C}^n \to \mathbb{C}^n$ and a finite set of points $X = \{x_1, \ldots, x_k\} \subset \mathbb{C}^n$ such that if x_j is an approximate solution with associated solution ξ_j, then $Df(\xi_j)$ is invertible.
Output: A set $A \subset X$ consisting of certifiable approximate solutions to f with $numA = |A|$, a set $D \subset A$ consisting of points which have distinct associated solutions with $numD = |D|$, and, if applicable, a subset $R \subset D$ consisting of points which have real associated solutions with $numR = |R|$.
Begin:
(1) Set $A :=$ **CertifySolns**(f, X) and $numA := |A|$.
(2) Enumerate the points in A as $a_1, \ldots, a_{numA}$.
(3) For $j = 1, \ldots, numA$, set $s_j := True$.
(4) For $j = 1, \ldots, numA$ and for $k = j+1, \ldots, numA$, if s_j and s_k are $True$, set $s_k :=$ **CertifyDistinctSoln**(f, a_j, a_k).
(5) Set $D := \{a_j \mid s_j = True\}$ and $numD := |D|$.
(6) Initialize $R := \{\}$ and $numR := 0$.
(7) If N_f is a real map, do the following:
  (a) Enumerate the points in D as $d_1, \ldots, d_{numD}$.
  (b) For $j = 1, \ldots, numD$, if **CertifyRealSoln**(f, d_j) is True, update $R := R \cup \{d_j\}$.
  (c) Set $numR := |R|$.

3. Overdetermined polynomial systems

When $N > n$, the polynomial system $f : \mathbb{C}^n \to \mathbb{C}^N$ is overdetermined. Dedieu and Shub [12] studied the overdetermined Newton's method whose iterates are defined by

$$N_f(x) \;:=\; x - Df(x)^{\dagger} f(x)\,, \tag{6}$$

where $Df^{\dagger}(x)$ is the Moore-Penrose pseudoinverse of $Df(x)$ [17, § 5.5.4] to determine conditions that guarantee quadratic convergence. Since the fixed points of N_f may not be solutions to the overdetermined polynomial system f, this approach cannot certify solutions to overdetermined polynomial systems.

A second approach is to certify that points are associated solutions to random square subsystems, using the algorithms of § 2. An additional level of security may be added

by certifying that, for a given point which is an approximate solution to two or more random square subsystems, the associated solutions lie within a given distance of each other. As with the overdetermined Newton's method (6), this also cannot certify solutions to overdetermined polynomial systems.

Let $R \in \mathbb{C}^{n\times N}$ be a matrix, considered as a linear map $\mathbb{C}^N \to \mathbb{C}^n$ and consider the square polynomial system $\mathcal{R}(f) : \mathbb{C}^n \to \mathbb{C}^n$ defined by $\mathcal{R}(f)(x) = R \circ f(x)$. Since $\mathcal{V}(f) \subset \mathcal{V}(\mathcal{R}(f))$ for any R, we call $\mathcal{R}(f)$ a *square subsystem* of f. If R is generic and $x \in \mathcal{V}(f)$, then x is a regular isolated solution to f if and only if x is a regular isolated solution to $\mathcal{R}(f)$. Moreover, if $x \in \mathcal{V}(\mathcal{R}(f)) \setminus \mathcal{V}(f)$, then x is a regular isolated solution to $\mathcal{R}(f)$. See [37] for more properties of random square subsystems $\mathcal{R}(f)$.

Suppose that R_1, $R_2 \in \mathbb{C}^{n\times N}$ are generic and $\mathcal{R}_i(f) = R_i \circ f$ for $i = 1$ and $i = 2$. Set $K = \text{null } R_1 \cap \text{null } R_2 \subset \mathbb{C}^N$ and $L = \{f(x) \mid x \in \mathbb{C}^n\} \subset \mathbb{C}^N$. Thus, K is general linear space of dimension $\max\{N - 2n, 0\}$ passing through the origin and L has dimension at most n possibly passing through the origin. As K is general, dimension-counting implies that $K \cap L \subset \{0\}$ and thus

$$\mathcal{V}(\mathcal{R}_1(f)) \cap \mathcal{V}(\mathcal{R}_2(f)) \;=\; \mathcal{V}(f)\,.$$

In addition, suppose that x is an approximate solution to both $\mathcal{R}_1(f)$ and $\mathcal{R}_2(f)$ with associated solutions ξ_1 and ξ_2, respectively. For $k \in \mathbb{N}$, define $x_{i,k} = N^k_{\mathcal{R}_i(f)}(x)$ for $i = 1, 2$. If $\xi_1 \neq \xi_2$, there exists $k \in \mathbb{N}$ such that

$$\|x_{1,k} - x_{2,k}\| \;>\; 2(\beta(\mathcal{R}_1(f), x_{1,k}) + \beta(\mathcal{R}_2(f), x_{2,k}))\,,$$

certifying that $\|\xi_1 - \xi_2\| > 0$.

If $\xi_1 = \xi_2$, then, for any $\delta > 0$, there exists $k \in \mathbb{N}$ such that

$$\|x_{1,k} - x_{2,k}\| + 2(\beta(\mathcal{R}_1(f), x_{1,k}) + \beta(\mathcal{R}_2(f), x_{2,k})) \;<\; \delta$$

certifying that $\|\xi_1 - \xi_2\| < \delta$. In particular, this shows that the solutions ξ_1 and ξ_2 to $\mathcal{R}_1$ and $\mathcal{R}_2$ associated to the common approximate solution x lie within a distance δ of each other. For $\delta \ll 1$, this *heuristically* shows that $\xi_1 = \xi_2$.

In summary, if a point is an approximate solution to two generic random subsystems with distinct associated solutions, a certificate can be produced demonstrating this fact. Also (but not conversely) for any given tolerance $\delta > 0$, a certificate can be produced that the distance between the associated solutions to the two subsystems is smaller than δ.

An additional test using the function residual could be added to this process. The following lemma describes such a test.

Lemma 6. *Let $f : \mathbb{C}^n \to \mathbb{C}^N$ be an overdetermined polynomial system, $R \in \mathbb{C}^{n\times N}$ be generic, and x be an approximate solution to $\mathcal{R}(f) := R \circ f$ with associated solution ξ such that $\alpha(\mathcal{R}(f), x) \leq 0.0125$. Then there exists $\epsilon > 0$ such that if there exists $y \in \mathbb{C}^n$ satisfying*

$$\|x - y\| \;\leq\; \frac{1}{40\gamma(\mathcal{R}(f), x)} \qquad \textit{and} \qquad \|f(y)\| \;<\; \epsilon\,,$$

then $\xi \in \mathcal{V}(f)$.

Proof. Define $\nu = \dfrac{1}{40\gamma(\mathcal{R}(f),x)}$ and $B(x,\nu) = \{y \in \mathbb{C}^N \mid \|x-y\| \leq \nu\}$. Since

$$\|x-\xi\| \;\leq\; 2\beta(\mathcal{R}(f),x) \;=\; \frac{2\alpha(\mathcal{R}(f),x)}{\gamma(\mathcal{R}(f),x)} \;\leq\; \frac{0.025}{\gamma(\mathcal{R}(f),x)} \;=\; \nu\,,$$

$\xi \in B(x,\nu)$. Moreover, Theorem 4 yields that $B(x,\nu) \cap \mathcal{V}(\mathcal{R}(f)) = \{\xi\}$.

Assume $\xi \notin \mathcal{V}(f)$. Since $\mathcal{V}(f) \subset \mathcal{V}(\mathcal{R}(f))$, $B(x,\nu) \cap \mathcal{V}(f) = \emptyset$. In particular, $g(z) = \|f(z)\|$ is positive on the compact set $B(x,\nu)$. Thus, there exists $\epsilon > 0$ such that $\|f(y)\| \geq \epsilon$ for all $y \in B(x,\nu)$. □

Remark 7. For Lemma 6 to give an algorithm, we would need a general bound for the minimum of a positive polynomial on a disk. In cases when such a bound is known, e.g., [24], the bound is too small to be practical.

4. Implementation details for **alphaCertified**

The program **alphaCertified** is written in C and depends upon GMP [19] and MPFR [14] libraries to perform exact rational and arbitrary precision floating point arithmetic. When the user selects to use rational arithmetic, all internal computations are *certifiable*. Due to prohibitive bit length growth of rational numbers under algebraic computations, **alphaCertified** allows the user to select the use of floating point arithmetic to speed up computations and conserve memory. Since floating point errors from internal computations are not fully controlled, **alphaCertified** only yields a *soft certificate* when using the floating point arithmetic option.

Three input files are needed to run **alphaCertified**. These files contain the polynomial system, the list of points to test, and the user-defined settings. See [22] for more details regarding exact syntax of these files. The polynomial system is assumed to have (complex) rational coefficients and described in the input file with respect to the basis of monomials. That is, the user inputs the coefficient and the exponent of each variable for each monomial term in each polynomial of the polynomial system.

The set of points to test are assumed to have either rational coordinates if using rational arithmetic or floating point coordinates if using floating point arithmetic.

The list of user-defined settings includes the choice between rational and floating point arithmetic, the floating point precision to use for the basic computations if using floating point arithmetic, and which certification algorithm to run. The user can also define a value, say $\tau > 0$, such that, for each certifiable approximate solution, the associated solution will be approximated to within $10^{-\tau}$ and printed to a file.

The specific output of **alphaCertified** depends upon the user-defined settings. In each case, an on-screen table summarizes the output as well as a file that contains a human-readable summary for each point. The other files created are machine-readable files that can be used in additional computations.

Linear solving operations are performed using an LU decomposition and the spectral matrix norm is bounded above using the Frobenius norm. When using rational arithmetic, **alphaCertified** avoids taking square roots whenever possible. When a square root is

needed, say for $a \in \mathbb{Q}_{>0}$, given $\nu > 0$, **alphaCertified** computes $b \in \mathbb{Q}_{>0}$ such that

$$\sqrt{a} \;\leq\; b \;\leq\; \sqrt{a} + 10^{-\nu}\,.$$

When using floating point arithmetic, the internal working precision is increased when updating the point via a Newton iteration, for instance in Step (d) of **CertifyDistinctSoln** and Step (d) of **CertifyRealSoln**.

When f is a square polynomial system in n variables, **alphaCertified** determines if N_f is real map using the following three tests. The first test determines if all of the coefficients of f are real. The second and third tests utilize a random rational point $y \in \mathbb{R}^n$ in the unit disk. The second test determines if $\{f_1(y), \ldots, f_n(y)\} = \{\overline{f_1(y)}, \ldots, \overline{f_n(y)}\}$, that is, as sets, f is invariant under conjugation. The third test computes $N_f(y)$ and determines if it is real. Each of these tests are performed using rational arithmetic.

The user instructs **alphaCertified** whether to only utilize the first test, utilize the first and second tests, or utilize all three tests. These tests are performed in order until either one of them succeeds or all of the tests that the user would like to employ fail. The real certification algorithm is bypassed if none of the employed tests conclude that N_f is a real map.

The user also has the option to bypass these tests and declare that N_f is a real map. In this case, for each approximate solution x with associated solution ξ, **alphaCertified** determines if there exists a real approximate solution that also corresponds to ξ. Notice that if the user incorrectly identified N_f as a real map, then ξ may not be real. Therefore, **alphaCertified** displays a message informing the user about what it actually has computed.

For an overdetermined polynomial system f, **alphaCertified** only checks to see if all of the coefficients of f are real. In this case, **alphaCertified** randomizes f using real matrices so that $N_{\mathcal{R}(f)}$ is always a real map.

5. Computational examples

We used **alphaCertified** to study four examples of naturally occurring polynomial systems where the number of real solutions is relevant. Two are from kinematics, while the other two are from enumerative geometry. All involve polynomial systems that are not easily solved using certified methods from symbolic computation.

The files used in the computations, as well as instructions for their use, are found on our website [22].

For the computations of Sections 5.3 and 5.4, we used nodes of the Brazos cluster [10] that consist of two 2.5 GHz Intel Xeon E5420 quad-core processors.

5.1. **Stewart-Gough platform.**

We used **alphaCertified** to certify a result of Dietmaier concerning the maximum number of assembly modes of a Stewart-Gough platform. This is a parallel manipulator in which six variable-length actuators are attached between a fixed frame (the ground) and a moving frame (the platform) [18, 39]. Each position of the platform uniquely determines the lengths of the six actuators. However, the lengths of the actuators do not uniquely determine the position and orientation of the platform, as there are typically several assembly modes, which we call *positions*.

A generic platform with generic actuator lengths has 40 complex assembly modes. Dietmaier [13] used a continuation method to find a Stewart platform and leg lengths for which all 40 positions are real. While his formulation as a system of polynomial equations and conclusions about their solutions being real have been reproduced numerically (this is a problem in Verschelde's test suite [42]), these computations only give a heuristic verification of Dietmaier's result.

We modified Verschelde's formulation (which is true to Dietmaier's paper), converting floating point parameters to rational numbers and then ran PHCpack [40] on the resulting polynomial system to obtain numerical solutions to the system. PHCpack found 40 solutions, each of which it identified as real. After converting the floating point coordinates of the solutions to rational numbers, we ran **alphaCertified** using these rational polynomials and rational points. It verified that these 40 points correspond to distinct solutions, and each corresponds to a real approximate solution. This gives a rigorous mathematical proof of Dietmaier's result.

5.2. **Four-bar linkages.** In [32], Wampler, Morgan, and Sommese solve the nine-point path synthesis problem for four-bar linkages. That is, they determined all four-bar mechanisms whose workspace curve contains nine given points. Using homotopy continuation, for nine generic points $\mathcal{P} = \{P_0, \ldots, P_8\} \subset \mathbb{C}^2$, the resulting polynomial system is shown to have 8652 regular isolated solutions. Due to a two-fold symmetry, there are 4326 distinct four-bar linkages which appear in 1442 groups of three, called Roberts cognates. We used **alphaCertified** to certify that the polynomial system has at least 8652 isolated solutions and, for a specific set of nine real points, certified the number of real solutions among these 8652 solutions.

If $\mathcal{P} \subset \mathbb{R}^2$, and we use the formulation in [32], the resulting polynomial system is not real. Taking the usual approach of writing the variables using real and imaginary parts, we generate a polynomial system consisting of four quadratic and eight quartic real polynomials given $\mathcal{P} \subset \mathbb{R}^2$.

Fix nine points $\mathcal{P} = \{P_0, \ldots, P_8\} \subset \mathbb{C}^2$. The resulting polynomial system $f_{\mathcal{P}} : \mathbb{C}^{12} \to \mathbb{C}^{12}$ depends upon the variables

$$\{a_1,\, a_2,\, n_1,\, n_2,\, x_1,\, x_2,\, b_1,\, b_2,\, m_1,\, m_2,\, y_1,\, y_2\}\,.$$

Define the complex numbers

$$\begin{array}{lll} a = a_1 + \sqrt{-1}\cdot a_2, & n = n_1 + \sqrt{-1}\cdot n_2, & x = x_1 + \sqrt{-1}\cdot x_2, \\ b = b_1 + \sqrt{-1}\cdot b_2, & m = m_1 + \sqrt{-1}\cdot m_2, & y = y_1 + \sqrt{-1}\cdot y_2, \end{array}$$

whose complex conjugates are $\overline{a}, \overline{n}, \overline{x}, \overline{b}, \overline{m}, \overline{y}$, respectively. These correspond to the variables used in the formulation in [32]. The four quadratic polynomials of $f_{\mathcal{P}}$ are

$$\begin{array}{rclcrcl} f_1 &=& n_1 - a_1x_1 - a_2x_2\,, & \quad & f_2 &=& n_2 + a_1x_2 - a_2x_1\,, \\ f_3 &=& m_1 - b_1y_1 - b_2y_2\,, & & f_4 &=& m_2 + b_1y_2 - b_2y_1\,. \end{array}$$

The eight quartic polynomials depend upon $\mathcal{P}$, in particular, upon the displacements from P_0 to the other points P_j. For $j = 1, \ldots, 8$, define $Q_j := (Q_{j,1}, Q_{j,2}) = P_j - P_0$ and write

each displacement Q_j using *isotropic coordinates*, namely $(\delta_j, \overline{\delta}_j)$ where

$$\delta_j = Q_{j,1} + \sqrt{-1} \cdot Q_{j,2} \text{ and } \overline{\delta}_j = Q_{j,1} - \sqrt{-1} \cdot Q_{j,2}.$$

For $j = 1, \ldots, 8$, the quartic polynomial f_{4+j} of $f_{\mathcal{P}}$ is

$$f_{4+j} := \gamma_j \overline{\gamma}_j + \gamma_j \gamma_j^0 + \overline{\gamma}_j \gamma_j^0$$

where

$$\gamma_j := q_j^x r_j^y - q_j^y r_j^x, \qquad \overline{\gamma}_j := r_j^x p_j^y - r_j^y p_j^x, \qquad \gamma_j^0 := p_j^x q_j^y - p_j^y q_j^x$$

and

$$p_j^x := \overline{n} - \overline{\delta}_j x, \qquad q_j^x := n - \delta_j \overline{x}, \qquad r_j^x := \delta_j(\overline{a} - \overline{x}) + \overline{\delta}_j(a - x) - \delta_j \overline{\delta}_j,$$

$$p_j^y := \overline{m} - \overline{\delta}_j y, \qquad q_j^y := m - \delta_j \overline{y}, \qquad r_j^y := \delta_j(\overline{b} - \overline{y}) + \overline{\delta}_j(b - y) - \delta_j \overline{\delta}_j.$$

Our first test certified that, for nine random points, the resulting polynomial system has at least 8652 isolated solutions. Since the displacements Q_j actually define the polynomial system, we choose the displacements to be random rational complex points with each coordinate having unit modulus. In particular, each coordinate of Q_j was of the form

$$\frac{t^2 - 1}{t^2 + 1} + \sqrt{-1} \cdot \frac{2t}{t^2 + 1}$$

where t was a quotient of two ten digit random integers. We used regeneration [21] in Bertini [4] to compute 8652 points that were *heuristically* computed to be within 10^{-100} of an isolated solution for $f_{\mathcal{P}}$. Then, **alphaCertified** certified that these 8652 points are indeed approximate solutions to $f_{\mathcal{P}}$ whose associated solutions are distinct.

Our second test certified the number of real solutions for a specific set of nine real points, namely Problem 3 of [32]. The nine real points are listed in Table 2 of [32], which, for convenience, we list the values of δ_j in Table 1. Since the points are real, $\overline{\delta}_j$ is simply

TABLE 1. Values of δ_j for Problem 3 of [32]

j	δ_j
1	$0.27 + 0.1\sqrt{-1}$
2	$0.55 + 0.7\sqrt{-1}$
3	$0.95 + \sqrt{-1}$
4	$1.15 + 1.3\sqrt{-1}$
5	$0.85 + 1.48\sqrt{-1}$
6	$0.45 + 1.4\sqrt{-1}$
7	$-0.05 + \sqrt{-1}$
8	$-0.23 + 0.4\sqrt{-1}$

the conjugate of δ_j. We used parameter continuation in Bertini to solve the resulting polynomial system starting from the 8652 solutions to the polynomial system solved in the first test. This generated a list of 8652 points which **alphaCertified** certified to be

approximate solutions that have distinct associated solutions of which 384 are real. In particular, **alphaCertified** certified the results reported in Table 3 of [32] for Problem 3, namely, that 64 of the 1442 mechanisms are real.

Figure 1 shows three of the 64 real mechanisms that solve this synthesis problem, together with their workspace curves. The first has two assembly modes with the workspace

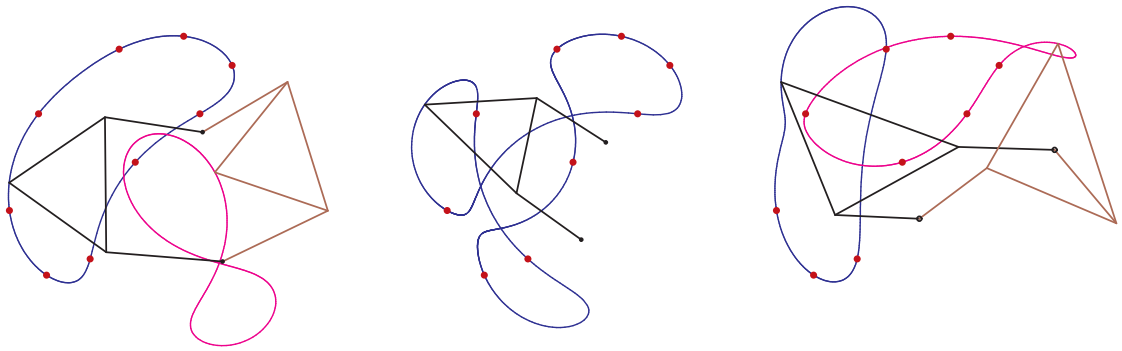

FIGURE 1. Three solutions.

curve of one mode a simple closed curve that contains the nine target points. This mechanism is the only viable mechanism among the 64 real mechanisms. The second has only one assembly mode, but its workspace curve is convoluted and does not meet the target points in a useful order. The third has two assembly modes, and each can reach only a proper subset of the target points.

5.3. **Lines, points, and conics.** We consider geometric problems of plane conics in $\mathbb{C}^3$ that meet k points and $8-2k$ lines for $k = 0, \ldots, 4$. When the points and lines are general, the numbers of plane conics are known and presented in Table 2.

TABLE 2. Numbers of plane conics

k	4	3	2	1	0
Number of conics	0	1	4	18	92

This problem is from a class of problems in enumerative geometry—counting rational curves—that has been of great interest in recent years [15]. For problems of enumerating rational curves of degree d in the plane that interpolate $3d-1$ real points, Welschinger [41] defined an invariant W_d which is a lower bound on the number of real rational curves, and work of Mikhalkin [30] and of Itenberg, Kharlamov, and Shustin showed that W_d is positive and eventually found a formula for it [23].

We used **alphaCertified** to investigate the possible numbers of real solutions to these problems of conics when their input data (points and lines) are real. Of particular interest is the minimum number of solutions that are real. Our experimental data suggests that when $k = 1$ at least two of the solutions will be real, and it shows that for $k = 0, 2$, it is possible to have no real solutions.

This computation used random instances of the problem. The coordinates of points were taken to be the quotient of two ten digit random integers, and the real lines were taken to be lines through two such random points. The resulting polynomial system was square. Each real instance was solved by Bertini [4] using a straight line parameter homotopy starting with a fixed random complex instance (see [37] for more details). Upon computing points that are *heuristically* within 10^{-75} of each isolated solution for the real instance, **alphaCertified** was used to certify the results of Bertini. In particular, it certified that all points computed by Bertini were approximate solutions whose corresponding solutions were distinct, and it certified the number of real solutions. Since enumerative geometry provides the generic root count, a certificate from **alphaCertified** yields a post-processing certificate that Bertini has indeed computed an approximate solution corresponding to each solution to the polynomial system. In every instance that Bertini successfully tracked every path, the heuristic results of Bertini matched the certified results of **alphaCertified**. Out of the over 1,450,000,000 paths tracked, 76 paths were truncated by Bertini due to a fail-safe measure. Thirty-two paths were truncated since they needed more than the fail-safe limit 10,000 steps along the path. Each of these paths were successfully tracked when the limit was raised to 25,000 steps. Forty-four paths were truncated since the adaptive precision tracking algorithm [5, 6, 3] requested to use more than the fail-safe limit of 1024-bit precision. Each of these paths were successfully tracked when the fail-safe limit was raised to 1284-bit precision.

The first interesting case is when $k = 2$ and there are four conics meeting two points and four lines. We solved 500 random real instances using the Brazos cluster. Each instance took an average of 0.7 seconds for Bertini to solve and 0.1 seconds for **alphaCertified** to certify the results. We found that there can be 0, 2, or 4 real solutions. Table 3 presents the frequency distribution of these 500 instances for this case.

TABLE 3. Frequency distribution for conics through 2 points and 4 lines

# real	0	2	4	total
frequency	12	221	267	500

When $k = 1$, there are 18 conics meeting a point and six lines in $\mathbb{C}^3$. We solved 1,000,000 random real instances using the Brazos cluster. Each instance took an average of 1.6 seconds for Bertini to solve and an average of 0.1 seconds for **alphaCertified** to certify the results. Every real instance that we computed had at least 2 real solutions. Table 4 presents the frequency distribution of these 1,000,000 instances for this case.

TABLE 4. Frequency distribution for conics through a point and 6 lines

# real	0	2	4	6	8	10	12	14	16	18	total
frequency	0	3281	21984	88813	193612	261733	226383	137074	53482	13638	1000000

To compare the performance of **alphaCertified** to symbolic methods, we computed 40,000 instances of the conic problem with $k = 1$ using Singular [11] to compute an eliminant that satisfies the Shape Lemma [7] and Maple to count the number of real roots of the eliminant, which is a standard symbolic method to determine the number of

real solutions to a zero-dimensional system of polynomial equations. The coordinates of points were taken to be rational numbers p/q where p, q were integers with $|p| < 4000$ and $0 < q < 1000$. Each computation took approximately 661 seconds on a single node of a server with four six-core AMD Opteron 8435 processors and 64 GB of memory. Table 5 presents the frequency distribution of these 40,000 instances for this case.

TABLE 5. Frequency distribution for conics through a point and 6 lines

frequency	0	146	892	3558	7739	10575	8965	5488	2089	548	40000

Finally, when $k = 0$, there are 92 plane conics meeting eight general lines in $\mathbb{C}^3$. We solved 15,662,000 random real instances using the Brazos cluster. Each instance took an average of 8.8 seconds for Bertini to solve and an average of 0.7 seconds for **alphaCertified** to certify the results. Table 6 presents the frequency distribution of these instances for this case.

5.4. **A Schubert problem.** Our last example concerns a problem in the Schubert calculus of enumerative geometry, which is a rich class of geometric problems involving linear subspaces of a vector space. Many problems in the Schubert calculus are naturally formulated as overdetermined polynomial systems. We investigate one such problem that can also be formulated as a square polynomial system using the approach of [2]. In particular, we demonstrate **alphaCertified**'s algorithms for overdetermined systems as well as investigate a conjecture on the reality of its solutions.

This problem involves four-dimensional linear subspaces (four-planes) H of $\mathbb{C}^8$ that have a non-trivial intersection with each of eight general three-planes $K_0, \ldots, K_7$. The Schubert calculus predicts 126 such four-planes. To formulate this Schubert problem, consider H to be the column space of a 8×4 matrix in block form

$$H \;=\; \begin{bmatrix} I_4 \\ X \end{bmatrix},$$

where I_4 is the 4×4 identity matrix and X is a 4×4 matrix of indeterminates. Represent a three-plane K as the column space of a 8×3 matrix of constants. Then the condition that H meets K non-trivially is equivalent to the vanishing of the determinants of the eight 7×7 square submatrices of the 8×7 matrix

$$A \;=\; [H\ K]\,. \tag{7}$$

In this standard formulation, the Schubert problem is a system of 64 equations in 16 indeterminates. Using a total degree homotopy to solve this would follow 4^{16} paths.

There is a second formulation which we used. Write K in block form,

$$K \;=\; \begin{bmatrix} \mathcal{K}_1 \\ \mathcal{K}_2 \end{bmatrix},$$

where $\mathcal{K}_1$ and $\mathcal{K}_2$ are 4×3 matrices. A linear dependency among the columns of A (7) is given by vectors $v \in \mathbb{C}^4$ and $w \in \mathbb{C}^3$ such that $Hv + Kw = 0$. Applying this to the different blocks of H and K gives

$$I_4 v + \mathcal{K}_1 w \;=\; 0 \qquad \text{and} \qquad X v + \mathcal{K}_2 w \;=\; 0,.$$

which is equivalent to $\widehat{A}w = 0$, where $\widehat{A} := \mathcal{K}_2 - X\mathcal{K}_1$. Thus H meets K non-trivially if and only if each 3×3 minor of $\widehat{A}$ vanishes. This gives a system $F_O(x)$ of 32 cubic polynomials in 16 indeterminates, which is more compact than the original formulation.

Our first test is to certify solutions to this overdetermined polynomial system F_O. We randomized F_O to maintain the structure of the equations as follows. For each $i = 0, \ldots, 7$ and $j = 1, 2, 3, 4$, let $f_{i,j}$ be the determinant of the submatrix created by removing the j^{th} row of the matrix $\widehat{A}_i$ corresponding to the ith three-plane. Then, for each j, we take four random linear combinations of the polynomials $f_{0,j}, f_{1,j}, \ldots, f_{7,j}$. This preserves the multilinear structure of the equations in the four variable groups corresponding to the columns of X. Solving this system using regeneration [21] finds 22,254 solutions. **alphaCertified** certified 126 of these solutions to be approximate solutions to two different (random) randomizations of F_O with associated solutions within a distance of $\delta = 10^{-10}$ of each other. The same result was also obtained using $\delta = 10^{-5}$. Thus, **alphaCertified** provided soft certificates that we found all 126 solutions to the Schubert problem.

This Schubert problem has an equivalent formulation as a square system. The columns of $\widehat{A}$ are linearly dependent if and only if there exists $0 \neq v \in \mathbb{C}^3$ such that $\widehat{A}v = 0$. For generic $\alpha_1, \alpha_2 \in \mathbb{C}$, this occurs if and only if there exists $y_1, y_2 \in \mathbb{C}$ such that

$$\widehat{A} \cdot \begin{bmatrix} y_1 \\ y_2 \\ \alpha_1 y_1 + \alpha_2 y_2 + 1 \end{bmatrix} \;=\; 0\,.$$

This formulation yields a system of 32 polynomials in 32 indeterminates, say $F_S(x, y^{(0)}, \ldots, y^{(7)})$. This polynomial system consists of 4 bilinear polynomials in x and $y^{(i)}$ for each $i = 0, \ldots, 7$. Since $y^{(i)}$ consists of two indeterminates, namely $y_1^{(i)}$ and $y_2^{(i)}$, a 9-homogeneous homotopy used to solve F_S would follow $\binom{4}{2}^8 = 6^8$ paths. As described in [2], we are interested in the components of $\mathcal{V}(F_S)$ having fibers with generic dimension zero. For

generic $K_0, \ldots, K_7$, since $\mathcal{V}(F_S)$ is zero-dimensional, $\mathcal{V}(F_O)$ and $\mathcal{V}(F_S)$ both consist of 126 isolated points and $\mathcal{V}(F_S)$ naturally projects onto $\mathcal{V}(F_O)$.

Our second test is to investigate the number of real solutions when we choose the three planes K_i as follows. For $t \in \mathbb{R}$, let $\gamma(t) = (1, t, t^2, \ldots, t^7) \in \mathbb{R}^8$ be a point on the moment curve. Select 24 rational numbers $t_1, \ldots, t_{24}$ and for $i = 0, \ldots, 7$, let K_i be the span of the three linearly independent vectors $\gamma(t_{3i+1})$, $\gamma(t_{3i+2})$, and $\gamma(t_{3i+3})$. When $t_1 < t_2 < \cdots < t_{24}$, the Secant Conjecture [16] posits that all 126 solutions will be real, but if the points are not in this or some equivalent order, then other numbers of real solutions are possible.

Since $K_0, \ldots, K_7$ are real, if we take the constants α_i to be real, then there is a correspondence between the real points of $\mathcal{V}(F_O)$ and the real points of $\mathcal{V}(F_S)$. We solved 25000 random real instances and certified that each had 126 real solutions.

Our third test investigated the number of real solutions when we choose the three planes K_i as follows. For $i = 0, \ldots, 7$, let $t_i \in \mathbb{C}$ be generic under the condition that $2k$ are complex conjugate pairs and $8 - 2k$ are real, where $0 \leq k \leq 4$. Define $K_i = T(t_i)$ where

$$T(t) = \begin{bmatrix} 1 & 0 & 0 \\ t & 1 & 0 \\ t^2 & 2t & 1 \\ t^3 & 3t^2 & 3t \\ t^4 & 4t^3 & 6t^2 \\ t^5 & 5t^4 & 10t^3 \\ t^6 & 6t^5 & 15t^4 \end{bmatrix}.$$

Then K_i is the three-plane osculating the moment curve at the point $\gamma(t_i)$. When $k = 0$, that is, when each t_i is real, this is the Shapiro Conjecture (MTV Theorem) [38, 33] and all 126 solutions are real. We tested 1000 such instances and for each, **alphaCertified** correctly identified all 126 solutions to be real. Our primary interest was when $k > 0$, for we wanted to test the hypothesis that there would be a lower bound to the number of real solutions if the set of osculating three-planes were real (that is, if $\{\overline{K_0}, \ldots, \overline{K_7}\} = \{K_1, \ldots, K_7\}$). This is what we found, as can be seen in the partial frequency table we give in Table 7. (To better show the lower bounds, we omit writing 0 in the cells with no observed instances.)

TABLE 7. Frequency distribution for the Schubert problem

	# real														
k	0	2	4	6	8	10	12	$\cdots$	18	20	22	$\cdots$	124	126	total
0								$\cdots$				$\cdots$		1000	1000
1				6	6	10	88	$\cdots$	554	1888	1832	$\cdots$	69	2021	42000
2						2614	3771	$\cdots$	3285	1579	1378	$\cdots$	1	38	24000
3						8896	4479	$\cdots$	1079	721	2586	$\cdots$			23500
4								$\cdots$			19134	$\cdots$		1	22500

This computation was part of a larger test of hypothesized lower bounds [20].

6. Conclusion

Smale's α-theory provides a way to certify solutions to polynomial systems, determine if two points correspond to distinct solutions, and determine if the corresponding solution is real. Using either exact rational or arbitrary precision floating point arithmetic, **alphaCertified** is a program which implements these α-theoretical methods.

We have also produced a Maple interface to **alphaCertified** to facilitate the construction of the input files needed.
